#### Electric Power Research Institute

The Electric Power Research Institute (EPRI) is an organization established by the U.S. utility industry in order to conduct and administer research in areas related to the generation, transmission, distribution and utilization of electric power. About a quarter of the institute's budget (\$36.2 million in 1975) is assigned to research projects related to the development of nuclear power.

In the area of neutron cross sections and associated nuclear constants, EPRI's objective is to provide the utility industry with a standard data base acceptable for use in power reactor applications and compatible with the requirements of ANSI standard N411.

The ENDF/B library, developed primarily under fast reactor funding, could provide the basis for such a standard provided its performance in thermal reactor applications can be improved. The major problem along this path concerns the apparent inability of the ENDF/B data to predict observed uranium-238 resonance capture rates in critical lattice experiments.

Since it is not clear whether the basic data, the methods of analysis, or the interpretation of lattice experiments is at fault, EPRI is supporting the National Neutron Cross Section Center to organize a working seminar of experts in each of the above areas in a format conducive to free discussions and exchange of ideas.

It is hoped that such a seminar will result in a better determination of areas where further research is most likely to yield a solution.

12

I consider the meeting to be an important one with considerable promise of being productive. It is a milestone in technology when a large number of people get together to try to investigate discrepancies, accelerate understanding and the application of that understanding. EPRI is to be commended for their endorsement of this work. I wish you all a very successful meeting.

#### INTRODUCTION

The National Neutron Cross Section Center is interested in U-238 resonance capture as part of i\*s responsibility for development of the Evaluated Nuclear Data File (ENDF/B), a library of microscopic data useful to both the research and applied communities. It is a prime objective that ENDF/B be application independent. Consistent results should be obtained when the best differential data are used to analyze integral experiments in configurations which average the nuclear properties of many neulides over energy and space.

Assembly of a comprehensive library of evaluated data is too massive a task for any one group. ENDF/B is developed with the help of the Cross Section Evaluation Working Group (CSEWG), a group of measurera, evaluators, and reactor physicists that meat regularly to plan, evaluate, and test nuclear data. In addition special groups of scientists are mobilized at times to study important problems. Part of CSEWG's program is the validation of ENDF/B data in the calculation of integral benchmark experiments. The attention of this Seminar is directed to the poor agreement obtained using ENDF/B data in the calculation of low enrichment uranium lattices. This is not a new problem but since configurations of this type continue to play and important rule in nuclear power, a field which is being increasingly scrutinized for technial flaws, all discrepancies should be tenaciously investigated until understood.

In the CSEWG experience, good cooperation among measurers, evaluators, and reactor physicists has been instrumental in bringing about improvements in ENDF/B. Each disciplinary group has shown a mutual respect for the potential precision inherent in differential and integral experiments and in calculational methods. These areas are sufficiently developed that it is now reasonable to expect that low enmichment uranium lattices should be well calculated from first principles. At present however this has not been done and the fault lies somewhere emong the nuclear data derived from measurements of basic data, the parameters interpreted from integral measurements, and the calculational methods.

~ vi -

In view of the past extensive investigations of this problem perhaps this Seminar cannot expect to develop any new insight. However, this Seminar does have the advantage of a time perspective of older information and consists of a large group of experts gathered in one place to have extended interactive discussion dedicated to this subject. The objective of this Seminar is to review past efforts, describe work in progress, and recommend new investigations aimed at understanding the inconsistency between differential and integral data. The Seminar is jointly sponsored by the Electic Power Research Institute, 3412 Hillview Avenue, P. O.Box 10412, Palo Alto, CA 94304 and the U. S. Energy Research and Development Administration, Washington, D. C. 20545.

ł

#### PROGRAM

There were five Sessions each devoted to an aspect of the effect of U-238 data on uranium lattice calculations. The Sessions and chairmen were selected with the help of the Thermsl Data Testing Group, headed up by F. J. McCrosson, operating within the Cross Section Evaluation Working Group.

The Sessions were divided according to the following topics:

Session	Topic	Chairman
I	Analysis of Critical and Subcritical Experiments	F. J. McCrosson, SRL
11	Experimental Differential Data	G. DeSaussure, ORNL
111	Resonance Analysis	M. R. Bhat, BNL
IV	Integral Measurements and Analysis	J. Hardy, Jr., BAPL
v	Methods for Calculating Energy and Spatial Self-Shielding Effects	R. Karam, GIT

Each Session, chairman was responsible for making arrangements with the speakers and organizing the discussion. After all speakers were heard the participants divided into working groups to prepare Session summaries and recommendations for future work. Papers submitted in the form of photo-ready copy are included in these proceedings.

#### FPILOGUE

After the Seminar there was an immediate exchange of information internal to the reactor physics calculations, the comparison of which would show where the reported disagreement between similar calculational methods entered. After correction of some differences in interpretation and some minor errors in long-standing versions of processing codes, most of the available reactor physics analyses of the benchmark lattices are in substantial agreement. At the Seminar confidence was not shaken in the parameters relating to uranium capture derived from lattice and rod measurements. Therefore, nuclear data continues to be suspected as the major source of the discrepancy although this is not obvious from examination of the measurements and their quoted uncertainty.

A useful background for the long standing discrepancy is presented in Paper No. 1 by Rothenstein. Monte Carlo calculations using ENDF/B-III data by Hardy in Faper No. 2 show that the discrepancy between calculation and experiment from previous values is reduced but not removed for TRX lattices even though thorough investigative techniques are employed. Monte Carlo methods reported by Rothenstein in Paper No. 20 were checked in part against Hardy's methods and showed that there were further small improvements using ENDF/B-IV data. In summary, there was relatively good agreement between calculated and measured reaction rate ratios and criticality for a wide range of metal to water ratios if Monte Carlo methods were used corresponding to a reduction in the disagreement between calculated and measured self shielded integrals from about 10 percent to 3 or 4 percent. The constant criticality bias and favorable calculated spectrum dependent reaction rate ratios gave strong indication that corrections to the data alone to accommodate remaining discrepancies would be severely restricted to avoid worsening calculated reaction rate ratios or introducing a composition dependent tilt in the criticality comparisons.

In the area of nuclear data future work is expected to concentrate on new experiments and reanalysis of existing data. New measurements are recommended that focus on the determination of resonance widths for the first few resonances for U-238, the magnitude of the capture cross section in the valleys between resonances and the transmission of neutrons through thick samples. Existing data will be examined for possible alternate choices of U-238 data that will lead to consistency within experimental uncertainties, differential cross sections and dilute and self shielded

- xi -

resonance integrals. For improved understanding of the discrepancy between calculation and experiment the sensistivity of the lattice benchmarks to reasonable choices of U-238 and other data will be investigated. As a result of the Seminar discussion, three papers by Bhat, Chrien, and deSaussure were submitted for inclusion in this compendia bearing on nuclear data and its analysis.

For more detailed comments the Session Summaries and Contributed Papers should be consulted.

#### Summary of Sessions I and IV

I. Analysis of Critical and Subcritical Experiments

IV. Integral Measurements and Analysis

F. J. McCrossen, SRL J. Hardy, Jr., BAPL

#### 1. SUMMARY OF LATTICE ANALYSES

Results of ENDF/B-III benchmark lattice calculations were summarized. These included calculations by the following (Tables 1 and 2):

F. Wheeler (ANC) -  $S_n$  / RABBLE

J. Hardy, Jr. (BAPL) - Monte Carlo (MUFT leakage corrections)

D. S. Craig and M. Hughes (CRNL) - Integral Transport/Nordheim

D. Mathews (GGA) - S / GAND3

L, Petrie (ORNL) - Monte Carlo

F. J. McCrosson (SRL) - Integral Transport/Nordheim

These results consistently indicate that criticality for low enrichment uranium lattices is underpredicted by approximately 2% and  $\rho^{28}$ , the ratio of epithermal-to-thermal <sup>238</sup>U captures, is overpredicted by approximately 10%. These discrepancies can be removed by a 1.0 ± 0.3 barn reduction of the effective resonance integral above 0.625 eV. The reasonably good prediction of criticality for the ORNL spheres of uranyl nitrate (93 wt % <sup>235</sup>U) indicates there are no significant deficiencies in the <sup>235</sup>U cross sections.

J. Askew described the extensive Winfrith experience in this area, which was first reported in the United States at the 1966 San Diego meeting on reactor physics in the resonance and thermal regions. With the U.K. cross section library, a reduction of about 0.5 h in effective resonance integral is required to predict <sup>238</sup>U capture in a large number of lattices. M. Edenius found the U.K. library to be 0.5 b lower than ENDF/B-III in effective capture integral. Hence, the Winfrith studies support the ~1.0 b reduction of ENDF/B-III effective capture integral suggested by CSEWG benchmark analyses.

The SRL results in Tables 1 and 2 provide a measure of the magnitude of the changes in going from ENDF/B-III to ENDF/B-IV. Although the improvement is substantial, much of the discrepancy remains. One of the primary objectives of the ENDF/B-IV <sup>238</sup>U cross section evaluation was to improve the prediction of thermal benchmark experiments, but accuracy of the differential measurements, as reported in the literature, gave little leeway for such improvement.

Because of the high degree of consistency among the hundreds of benchmarks considered over a wide range of leakages, pitches, enrichments and moderator types, it was concluded that there is a real discrepancy in the  $^{238}$ U epithermal capture cross sections which yields effective resonance integrals which are about 1.0 barn too high, and that our objective should be to localize where the deficiencies lie in the epithermal region. Reactor analysts have generally agreed that the reduction should be made in <u>unshielded</u> regions of the cross section, and this has been accomplished by a variety of artifices, e.g., a constant reduction in the capture cross section throughout the resonance region, or a reduction of keV p-wave cross sections.

- xvi -

のないないのであるというないのであるというないないないであるというであるというないのであるというないのであるというないのであるというないのであるというないのであるというないのであるというないのであるというないのである

1.

The consistency of the thermal reactor calculations can also be extended to the large plutonium fueled fast reactor benchmarks. Here the U-238 capture to Pu-239 fission rate ratios are, for the most part, high by 2-8 percent whereas the calculated eigenvalues are low by about 0.5 percent. There is also evidence that the screement between the calculated and measured parameters gets worse as the U-238 isotopic concentration increases (summary of CSEWG Meeting, October 23-24, 1974). It should be noted, however, that in fast reactor systems modifications to cross sections other than the U-238 capture cross section(e.g., the U-238 inelastic cross section) can improve the agreement between the calculated and measured values of the U-238 capture to Fu-239 fission rate ratios and the eigenvalues.

Two new calculational programs were presented at the meeting. W. Rothenstein (BNL) presented results from HAMMER calculations, but with the resonance reaction rates calculated by Monte Carlo (REPC). These calculations yielded good prediction of k and  $\rho^{28}$  using ENDF/B-IV. D. Finch (SRL) also presented results using integral transport theory and a new resonance treatment, similar to RABBLE, which yielded promising results. These new results offer the possibility that the problems with  $\rho^{28}$  might lie in the lattice analysis techniques and not in the differential cross sections (or the integral measurements). However, at this point this is rather improbable due to the good consistency among many previous calculations using similar techniques. For example, F. Wheeler's calculations used RABBLE for the resonance treatment, which should be similar to the new approach presented by D. Finch. J. Hardy used Monte Carlo (RECAP) calculations, which should include the advantages of the Rothenstein technique.

- xvii -

The Wheeler and Hardy calculations are consistent within themselves and support the need for a 1.0 barn reduction in the effective resonance integral. A comparison of the two methods is given below for the zero leakage cell calculations for TRX-1:

Parameter	Hardy	<u>Wheeler</u>	<u>% Diff.</u>
k	1.155	1.151	.3
م 2 <b>8</b>	1.375	1.407	2.3
δ <sup>28</sup>	0.0835	0.0835	0
δ <sup>25</sup>	0.1002	0.0999	.3
CR	0.814	0.796	2.3

#### 2. SUMMARY OF INTEGRAL MEASUREMENTS

R. Sher reviewed some of the activation methods used to measure  $^{238}$ U capture,  $^{238}$ U fission, and  $^{235}$ U fission rates in lattices. Emphasis was placed on the cadmium ratio method for  $\rho^{28}$ , the ratio of epithermal/thermal  $^{238}$ U capture. Among the sources of possible systematic error are neutron streaming, flux and source perturbation by experimental loadings, and calculation of the cadmium cutoff energy.

S. Fiarman and R. Sher presented calculational results for streaming effects caused by use of aluminum shields on  $^{238}$ U detector foils.

J. Hardy, Jr. discussed <sup>238</sup>U capture experiments in TRX lattices.  $\rho^{28}$ was measured by the cadmium ratio technique and also by thermal subtraction, which avoids the use of cadmium-covered <sup>238</sup>U foils (and associated questions of systematic error). The two methods gave consistent results.

- xviii -

D. Pellarin and W. Morris described recent parameter experiments in exponential assemblies of concentric-tube  $^{238}$ U lattices moderated with  $D_2^{0}$ . Included were measurements of  $^{238}$ U fission,  $^{235}$ U fission,  $^{238}$ U capture, and  $B^2$ . These lattices strongly emphasized spatial heterogeneity effects.

The following points were noted in the discussions:

#### a. Lattice Experiments

Overall consistency of results from a large number of experiments at different laboratories suggests that there are no serious systematic errors associated with <sup>238</sup>U capture measurements in lattices. (Because of the varied techniques employed, and the extreme range of lattice types and pitches covered, any such errors would have to be of a fundamental nature.) This conclusion is supported by the consistent calculation of low  $k_{eff}$  values, correlated with the amount of <sup>238</sup>U resonance capture. Consistency of the CSEWG benchmark experiments with those analyzed at Winfrith can be inferred from the fact that both indicate the need for a <sup>238</sup>U capture integral ~ 0.6 b below that required for isolated rod experiments (see Item c).

#### b. Isolated Rod Shielded Capture Experiments

These were reviewed by E. Hellstrand at the 1966 San Diego meeting. For  $UO_2$  rods, the average recommended values are slightly lower than Hellstrand's own measurements; for metal rods, the recommended values are appreciably higher. Calculations indicate that Hellstrand's own results are more consistent as to slope, and between  $UO_2$  and metal rods.

- xix -

Overall uncertainty is  $\pm$  3.5%. This type of measurement is subject to uncertainty of normalization and flux spectrum. Interpretation is less straight forward than for lattice measurements.

#### c. Consistency of Lattice and Isolated Rod Experiments

Analyses of lattice capture measurements and isolated rod shielded integrals have been made at Winfrith and by the CSEWG data testing committee. Both analyses conclude that the lattice experiments require  $\sim 0.6$  b less <sup>238</sup>U effective capture integral than do the isolated rod experiments. (This differs by only 0.1 b between Hellstrand's recommended values and his own results, but the latter give better overall consistency.) This difference is compatible with uncertainties assigned to the respective experiments. Lattice measurements are considered to be more cleanly interpretable, although they show some sensitivity to nuclear data other than the <sup>238</sup>U capture cross section.

Discussion of integral experiments, and additional references, may be found in the following reports:

 E. Hellstrand, "Measurement of Resonance Integrals," in Reactor Physics in the Resonance and Thermal Regions, Vol, II, p. 151, M.I.T. Press, 1966.

#### 3. RECOMMENDATIONS

<u>A.</u> Sensitivity of  $\rho^{28}$  to the resonance parameters of the first few <sup>238</sup>U resonances should be reviewed. It was indicated by experimentalists at this meeting and also the Saclay Specialists Meeting on Resonance Parameters of Fertile Nuclei and <sup>239</sup>Pu (e.g. NEANDC (E) 163U, p. 149) that uncertainties in  $\Gamma_n$  and  $\Gamma_\gamma$  for the first few resonances may be significantly greater than previously reported in the literature. Any revisions to the resonance parameters should be consistent with the measured value of the dilute resonance integral and should provide effective resonance integrals consistent with the Hellstrand data for isolated rods. Analyses of Doppler measurements, e.g., the work presented by M. Edenius in Session I, should be helpful in evaluating the merit of revisions to the cross sections.

<u>B.</u> The effects on  $c^{28}$  due to the proper inclusion of interference scattering from bound levels and the very high energy resonances should be further examined. The proper analysis was described in a paper by B. R. Leonard given at the 1972 Kiamesha Lake Conference (CONF-720901, P. 81). Presently ENDF/B ignores these effects which can be discerned in transmission measurements (see, for example, the presentation by D. Olsen (ORNL), Session II).

- xxi -

<u>C.</u> There should be a coordinated effort to qualify the calculational methods themselves. A systematic comparison of the techniques used by D. Finch, J. Hardy, W. Rothenstein, and F. Wheeler would provide valuable information concerning the inter-relationships of the various methods. Also, a documented comparison of the edits of ENDF/B to multigroup processing codes on a common group structure would serve to better define the starting point of the lattice calculations and provide valuable information to the developers of processing codes. Some limited work in this area has been done, but none of it has been adequately documented for thermal reactor applications.

<u>D.</u> The above work has been carried out to some extent, but the questions are still raised within the reactor community because the results have been inadequately published. This clearly suggests that, to avoid duplication and provide a more cohesive program, these efforts should be coordinated through specific funding to a single responsible organization, and the results made known to the general reactor community.

<u>E.</u> A detailed review should be made of the current most important techniques for measuring <sup>238</sup>U capture in lattices (e.g., modified conversion ratio; cadmium ratio and thermal subtraction methods for  $\rho^{28}$ ). Sources of systematic error should be evaluated and compared. Work in this area, funded by EPRI, is now in progress at Stanford.

- xxii -

ι.

 $\underline{F}_{\cdot}$  A review should be made of the major integral measurements of  $^{238}$ U capture in reactor lattices. This should include a comparison of techniques and results as well as an evaluation of reliability. Results should be compiled according to reactor types and the quality of the measurements. Comparison should be made with isolated rod results.

<u>G.</u> Three experiments were proposed for analyzing the <sup>238</sup>U capture cross section under heavily shielded conditions and localizing the discrepancy in energy:

1) Self-indication transmission measurements on a resonance-byresonance basis through thick samples of uranium. An experiment of this type was performed at RPI and analyzed by T. Byoun and R. Block in the unresolved resonance region. Data exists in the resolved region down to approximately 20 eV. Thus, the data for selected resonances could be analyzed at little cost to evaluate the merit of the information provided by this technique.

2) An experiment in which a small  $Cf^{252}$  source drives a surrounding homogeneous mixture of  $^{238}$ U and moderator. The moderator/ $^{238}$ U ratio would be varied to progressively soften the spectrum. The  $^{238}$ U capture/ source neutron would be measured and calculated. A liquid system (uranyl nitrate in H<sub>2</sub>O or D<sub>2</sub>O?) would greatly simplify the experiment, if feasible.

3) Time of flight spectrum measurements in heavily shielded  $\frac{238}{U}$  samples.

# Summary for Sessions II and III EXPERIMENTAL DIFFERENTIAL DATA AND RESONANCE ANALYSIS

G. de Saussure Oak Riāge National Laboratory

M. R. Bhat Brookhaven National Laboratory

Bill Havens stressed the importance of systematic errors and the lack of detailed information on such errors in published reports. Experimentalists should be encouraged to report in detail the main features of the experiment and analysis so as to allow an evaluator to independently determine errors and correlations among errors.

J. Felvinci reported on correlations between successive  $\Gamma_n^0$ . Statistical tests (using runs statistics and autocorrelations tests) show "intermediate structure" with 200 eV and 300 eV spacings. Such structure is not observed when the tests are applied either to random data or to the neutron widths of <sup>232</sup>Th. Apparent correlations between  $\Gamma_n^0$  and  $\Gamma_\gamma$  have also been observed.

D. K. Olsen reviewed the transmission measurements made since 1963 and reported the results of recent 40-m measurements from ORELA. A comparison of the ORELA transmissions with transmissions obtained from ENDF/B-IV showed a serious discrepancy in the total cross section between resonances. It was shown that a correct R-matrix calculation using ENDF/B-IV parameters reproduced the experimental differential data.

- xxiv -

R. C. Block discussed the filtered beam technique using an 8-in Fe filter; a peak is obtained around 24 keV with FWHM of 2 keV and a signalto-background ratio of 200. Block also reported on self-indication measurements done at RPI on samples at 80°K, 300°K, and 900°K.

R. B. Perez summarized the present status of <sup>238</sup>U capture above the resonance region. The various measurements agree in shape but there are large normalization uncertainties. Intermediate structure in the unresolved range was also discussed.

F. J. McCrosson reported on the ENDF/B-IV evaluation of the resonance parameters. There were not much more data available to the ENDF/B-IV evaluator than had been available for ENDF/B-III, however, the version III data tests results which were available underpredicted eigenvalues. Some p-wave levels of version III were eliminated from version IV.

Gert Rohr reported recent p-wave assignments made at the BCMN by looking at the high and low bias measurements of the gamma transitions. Also the experimental program on <sup>2 9 R</sup>U at Geel was discussed. This program includes measurements of scattering, transmission with sample cooled to liquid nitrogen temperature, self-indication and capture.

Derek Gayther discussed recent transmission measurements made by Moxon at Harwell through a 9-cm depleted uranium metal sample. Preliminary indications are that at least one small resonance previously assigned to be p-wave shows signs of a resonance-potential interference effect. It is planned to make further measurements with a 14-cm thick sample. Measurements to study Doppler effects in 16-cm thick  $UO_2$  samples are currently under way. Initially, transmission measurements will be made with the sample heated up to ~1800°C. It is hoped to also measure capture with a Moxon-Rae detector.

- xxv -

R. Chrien reported on measurements of capture cross sections for <sup>238</sup>U and other nuclei through an iron filter using activation techniques. The <sup>238</sup>U measurement was in excellent agreement with the RPI and Kyoto Univ. filtered beam results.

R. N. Hwang discussed the effect of level spacing correlations on the Doppler coefficient. A comparison of calculations using the Dyson statistics with calculations using the uncorrelated Wigner distribution was made. The effect of corrections was small except perhaps at extremely high temperatures.

Bo Leonard stressed the importance of doing an unbiased R-matrix calculation of scattering. The proper treatment for this is described in a paper at the 1970 Kiamesha Lake Conference and also in ENDF-153 (71).

H. Derrien could not attend the seminar but sent some "Comments on <sup>238</sup>U Width Evaluations" which were distributed to the participants and are included in the proceedings.

### Recommendations

We suggest that the errors of the first few levels of  $^{238}$ U be critically reevaluated.

A review of the transmission measurements of Jackson and Lynn on the 6.7-eV resonance reveals that their resonance parameters primarily depend on data obtained at 4°K combined with an Einstein phonon frequency distribution. Thus, the interpretation of this experiment differs from the gas model used in most differential and reactor neutronics interpretations of Doppler broadening. Jackson and Lynn obtained

> $\Gamma = 28.5 \pm 1.5 \text{ meV}$  $\Gamma_n = 1.52 \pm 0.01 \text{ meV}$

> > - xxvi -

「日本市政治法院には法律法法

Note that the  $\Gamma$  (and  $\Gamma_{\gamma}$ ) values of this experiment were misquoted in BNL-325 with errors of  $\pm$  0.4 meV. This error assignment was not a result of the measurement. The high accuracy of  $\Gamma_{n}$  is not supported by any details reported in the paper and is judged by this group to be unrealistic. We further note that there are four other experimental values reported in BNL-325 (1965) all of which report  $\Gamma_{\gamma}$  values lower than Jackson and Lynn with comparable precisions (21.2 - 26 meV). The average (unweighted) value of  $\Gamma_{\gamma}$  of the five experiments would be about 25 meV. We further note that de Saussure <u>et al</u>. reported, <u>Nucl.Sci. Eng. 51</u>, 385 (73), measurements of capture in a thick sample of this resonance. Dopplerbroadened, Monte Carlo corrected calculations of this resonance line with ENDF/B-III gave a broader resonance in the wings than observed in the experiment. Since ENDF/B-III gave  $\Gamma_{\gamma} \approx 25.6$  meV, the implication is that perhaps the true value of  $\Gamma_{\gamma}$  is smaller than this.

We further note that the  $\Gamma_{\gamma}$  values deduced from analyses of different experiments of the next few strong s-wave resonances produce a significantly large spread of values. The plots of  $\Gamma_n$  vs  $\Gamma_{\gamma}$ , <u>e. g.</u>, shown by Poortmans <u>et al</u>. [NEANDC(E) 163U, pp 155-156] typically show ranges of experimental values of 5 meV for resonances between  $E_0 = 36.7$  eV and 116.8 eV. Thus, it appears that evaluated  $\Gamma_{\gamma}$  values for these resonances have produced uncertainties which are unrealistically small. Thus, this group feels that values in the range 20 to 25 meV for the first few s-wave resonances do not violate the existing differential data.

- xxvii -

主要なしたとしては認識でおいれた。「ないない」となってないにはないないです。

The group recommends studies of benchmark experiments in which the  $\Gamma_{\gamma}$  values of these resonances are systematically and uniformly perturbed to determine quantitatively the effect on the benchmark parameters. In performing these perturbations, care should be taken to adjust the l/v component of capture in the smooth file to provide continuity with the ENDF/B-IV thermal smooth capture file at 1 eV.

B. We recommend that a proper R-matrix treatment of the total cross section be adopted by ENDF/B, and that this treatment be tested by comparison with experimental differential data over the entire resolved resonance range and below.

C. We recommend that the systematic discrepancies between Columbia, the BCMN and JAERI neutron widths above 1.5 keV be further investigated, in particular, by using the same method of analysis on all sets of data (as suggested by H. Derrien).

D. We recommend that all observed p-wave levels by included in the ENDF/B file and that a p-wave strength function of  $2.2 \pm .2 \times 10^{-4}$  be used to make up missed levels in the resolved range and in the unresolved range.

E. The present ENDF/B-IV strength functions appear low compared to the most recent experimental evidence.

F. We recognize that there is a possibility that there are capture and scattering width correlation, those correlations could possibly explain the discrepancy between calculation and data. If the discrepancy can be explained entirely by the correlation, we recommend that an intensive study be done.

G. Recent measurements of gamma transitions by Ed Jurney (LASL) indicate that there is probably no p-wave level below the Cd cutoff.

- xxviii -

H. We recommend a careful measurement of the shape of the 6.7-eV capture resonance to see if any asymmetry is present.

I. We recommend performance of self indication (S.I.) measurements with different sample thicknesses and temperature. We recommend that RPI S.I. measurements be further analyzed.

J. We recommend that a group of experimentalists and reactor physicists collaborate in designing a set of S.I. measurements to be used as benchmarks to test <sup>23+1</sup>U data and calculation methods.

K. The two alternate data adjustments used as a contrivance by reactor physicists to make the differential data in agreement with integral experiments are (1) subtract about .2 b of capture cross section from 4 eV to 9.12 keV; (2) reduce the p-wave capture integral by about 1b. These adjustments appear totally incompatible with our present knowledge of differential data.

#### Summary for Session V R. A. Karam, GIT

METHODS OF CALCULATING ENERGY AND SPATIAL SELF-SHIELDING EFFECTS

Members of the committee on "Methods for Calculating Energy and Spatial Self-Shielding Effects," Session V, made the recommendations given below which were adopted by all attendees of the Seminar. Members of the Committee were Don R. Finch, Savannah River Laboratory; Richard Hwang and Phil Kier Argonne National Laboratory; Rubin Goldstein, Combustion Engineering; Wolfgang Rothenstein and Arthur Buslik, Brookhaven National Laboratory; R. A. Karam (chairman), Georgia Institute of Technology.

A. There is a need to investigate the possible effects of the use of the free gas model in neutron slowing down in tightly bound atoms in crystalline lattices on resonance capture. This will require a study of the phonon spectrum in the uranium metal, uranium oxide, and uranium carbide lattices. If this theoretical investigation suggests that there are significant effects, the possibility of defining a relevant experimental program should be looked into. In addition a study should be made of the influence of this effect on Doppler broadening. (See "Effects of the Free-Gas, Slowing-Down Model on Resonance Cross Sections in  $^{238}$ U.")

B. The treatment of the Unresolved Resonance Region appears to be adequate for thermal reactor analysis.

C. Discrepancies have been noted during the Seminar on  $^{238}U$  Resonance Capture between the results of various codes. The discrepancies of most concern refer to different Monte Carlo codes which have been used for some

- xxx -

benchmark studies. Some of the differences may be due to the use of ENDF/B-III in some calculations and ENDF/B-IV in others; the effect of the cross section changes will be evaluated. However, spart from cross section data differences, there appear to be anomalies which must be resolved. Of prime importance is the calculated value of the capture fraction of neutrons in  $^{238}$ U in a simple benchmark lattice normalized similarly in the Monte Carlo codes used at Westinghouse and ENL. In this connection the resonance profiles in both Monte Carlo codes, as well as the energy grids and Doppler broadening techniques employed in their generation, should be compared in detail. Additional parameters that can be computed by all codes using the same data base are the following:

- 1. The thermal neutron captures in  $^{238}$ U per neutron slowing down past 0.625 eV.
- 2. The thermal fissions in  $^{235}$ U per neutron slowing down past 0.625 eV.
- The ratio of A and B represents a number that can be used as a consistency check between experiment and calculation (see E below).
- 4. The <sup>238</sup>U fission per neutron from thermal fission injected into the lattice.

D. With regard to the advantages and disadvantages of different calculational procedures the following points should be noted:

 The Nordheim resonance treatment may not be sufficiently accurate for thermal reactor benchmark calculations. Some of the reasons for this are the isolated resonance approximation, the limited extent of the numerical integration covering each resonance with - xxxi -

the need for simple algorithms to cover wing corrections, and the flat flux approximation.

 Integral transport and Monte Carlo methods do not have these difficulties.

The integral transport method has the advantages of computing detailed flux distributions in space and energy. A leakage buckling term can be used if desired. Running times are relatively short compared to the Monte Carlo method. The shortcomings of integral transport methods include the difficulty of including anisotropic scattering in the laboratory system, the use of a cylindricized outer boundary with an isotropic return boundary condition in a one-dimensional code, and the use of cosine currents to evaluate collision probabilities in some of the codes currently employed.

Monte Carlo methods have the advantage of treating complex geometries, anisotropic scattering, and can in general model the physical problem accurately. On the other hand small regions in space or energy may present statistical problems unless special methods, such as adjoint Monte Carlo, are employed. The advantages are, however, offset to some extent by the long running times required to attain adequate statistics. If Monte Carlo methods are used in conjunction with other codes, such as multigroup codes, care must be exercised in how they are interfaced.

A full three-dimensional Monte Carlo study of some of the lattice benchmarks might be useful.

It was noted that Monte Carlo methods might be used to study streaming and flux depression effects in foil activation experiments.

E. With regard to the choice of benchmarks, attention must be paid to the methods used to ensure that the most accurate integral parameters are

- xxxii -

1.

obtained. One suggested consistency check is the ratio of thermal captures in  $^{238}$ U, C<sup>28</sup> to the thermal fissions in  $^{235}$ U, F<sup>25</sup>. This quantity should be calculated accurately by any thermal spectrum code. It can also be related to the measured integral parameters by the expression:

$$\frac{c^{28}}{r^{25}} = CR^* \frac{(1+6^{25})}{(1+6^{28})}$$

where

 $CR^*$  = total capture in <sup>238</sup>U to total fissions in <sup>235</sup>U,  $\delta^{25}$  = the epithermal to thermal fissions in <sup>235</sup>U,  $\zeta^{28}$  = the epithermal to thermal captures in <sup>238</sup>U.

Additional benchmarks involving non Cd-covered as well as Cd-covered reaction ratios would be useful. The range of moderator to fuel ratios should also be extended.

#### Discrepancies in Thermal Reactor Lattice Analysis

W. Rothenstein Brookhaven National Laboratory Upton, New York 11973

#### Abstract

Experience gained over recent years has shown that the consistent use of ENDF/B data leads to discrepancies, when the results of analysis of thermal reactor lattices containing Uranium fuel of low enrichment are compared with experiment. Typically the effective multiplication factor is less than unity by one or two percent, and even as much as three percent for very tight water moderated lattices. Similar trends have been observed by investigators at Winfrith using their multigroup data.

It is the purpose of the seminar on U-238 Resonance Capture to examine the different areas which might lead to the observed discrepancies, and in particular to determine whether the problem is due to the quality of the microscopic nuclear data, the accuracy of the integral experiments, the approximations inherent in the lattice analysis, or a combination of all of these factors.

In the present paper the previous studies of clean thermal reactor lattices will be reviewed. The principal features of the calculational methods, which make full use of ENDF/B data, will be outlined and compared with other treatments specially as regards the resonance capture calculations.

The information which can be obtained from comparisons of measured integral lattice parameters and their calculated values will be discussed, together with attempts which have been made to use this information to reduce or eliminate the gap between theory and experiment.

- 2 -

#### I. INTRODUCTION

Thermal reactor lattices have been analyzed quite satisfactorily for many years. It might seem strange therefore that a seminar should be devoted to this topic at the present time.

Manna and a strategy and a strategy

It is of interest to note that those concerned with thermal reactor design report no problems regarding the agreement between their calculations and experiment. In particular, V. O. Uotinen of Babcock and Wilcox, in a review paper<sup>(1)</sup> at a recent Conference on Nuclear Cross Sections and Technology in Washington, D.C., March 1975, referred to the successful analysis of 17  $UO_2$  uniform lattices and 14 uniform  $UO_2$ -PuO<sub>2</sub> lattices, which led to values of  $k_{eff}$  differing from unity by not more than about 2 tenths of one percent. Similar accuracy was also reported in the analysis of non uniform lattices.

It was admitted however, that the analysis involved a certain amount of adjustment of the nuclear data and the calculational procedures in order to attain this degree of agreement between the experiments and the calculations.

At the APS meeting on Nuclear Cross Sections and Technology, the need for bias factors was also referred to by N. C. Paik<sup>(2)</sup> of Westinghouse in the analysis of LMFBR's, and J. Y. Barre of Cadarache<sup>(3)</sup> stressed the approach of relying heavily on integral data in Fast Breeder development.

On the other hand for a thorough understanding of reactor behavior, and in particular thermal reactors, it seems unsatisfactory that even the simplest lattices cannot be analyzed from the basic microscopic data without resorting to adjustments of one kind or another.

- 3 -

It was pointed out about six years ago, by J. Chernick, that in any attempt to reconcile calculations and experiments the three basic ingredients involved should be carefully investigated: the basic nuclear data, the integral experiments, and the approximations inherent in the lattice analysis. Clearly any discrepancies might be due to any one of these ingredients or to all in different proportions. It is frequently difficult to pin down exactly where the trouble lies. It is the aim of the Seminar on U-238 Resonance Capture to throw light on the causes responsible for the existing discrepancies and to stimulate further work in these areas.

### II. THE MAGNITUDE OF THE DISCREPANCIES

The discrepancies between lattice analysis and integral experiments have been evident since the early versions of the ENDF/B library. Table 1 shows some  $k_{eff}$  values for clean light water moderated lattices<sup>(4)</sup> These were based on ENDF/B-1 from which multigroup libraries were prepared for the HAMMER analysis code<sup>(5)</sup> It is apparent that the multiplication factor gets progressively worse the tighter the lattice.

TABLE 1

1.3% ENF	LICHED U-H O (H	EXAGONAL LATTICES)

3.0	59.25	0.9884
4.0	54.69	0.9991

- 4 -

A similar trend is observed in the case of some Würenlingen  $D_2O$  lattices<sup>(4)</sup> which are shown in Table 2.

	TABLE 2

14.0	6.47	0.9893	
16.0	5,06	0.9884	

It was realized at the outset that a weak link - and probably the weakest link - in the analysis is the resonance capture calculation. The shielding in these systems containing rods having very high U-238 density is very large, and small errors in its evaluation can influence the results of the analysis very considerably. The methods used at Brookhaven National Laboratory for evaluating the shielded resonance integrals are based on the Nordheim procedure<sup>(, c)</sup> which is relatively straightforward and rapid on a fast computer. The method involves a number of simplifications and assumptions, however, the most important of which are:

 In the resolved resonance region each resonance is treated separately as though it were entirely isolated. Contraction of the second

- A 1/E flux is assumed to be the asymptotic flux above the resonance, i.e., complete flux recovery between resonances is assumed.
- 3) In order to emphasize the energy variable by constructing a very fine energy grid, the spatial aspects of the problem are reduced to the use of two region collision probabilities for which tables are prepared.

- 5 -

- 4) The collision density is calculated over the central part of each resonance only by numerical integration of the slowing down integral equation. Unshielded end or wing contributions are used beyond this region.
- 5) The shielded resonance integral is generally assumed to contribute to the capture only in the energy group in which the peak is located<sup>(?)</sup>

In order to treat the resonance events more realistically without the need for simplifying assumptions, comparisons with Monte Carlo calculations have frequently been made. Such comparisons are also not free from problems quite apart from the statistical uncertainties of the Monte Carlo calculations. The results shown in Tables 1 and 2 for  $H_00$  and  $D_00$  lattices were in fact corrected so as to bring the Nordheim shielded resonance integrals in line with Monte Carlo estimates. The latter were obtained with a code<sup>(8)</sup> based on the Breit-Wigner Single Level formalism for which parameters are given in the ENDF/B files. The code used was quite cumbersome as a number of neighboring resonances had to be used to calculate the neutron cross sections at each energy point. Doppler Broadening line shape functions had to be evaluated for each contributing resonance. In addition it was necessary to use a simple algorithm to include the effect of distant resonances. The magnitude of the corractions which were applied to the calculated Nordheim resonance integrals are shown for U-238 in Fig. 1. They amount to a reduction of the shielded resonance integral by up to 10 percent for the  $D_0^0$  lattices. For the light water lattices the corrections were smaller,<sup>(4)</sup> about half this amount. The corrections applied to the U-235 resolved resonance integral are considerable as shown in Fig. 2. They were not determined very accurately at the time, but their effect on the lattice analysis is rather small, since

- 6 -

1.

most of the U-235 events occur at thermal energies. The reason for the large corrections in the case of U-235 lies in the fact that they are shielded by the U-238 resonances, an effect which is not taken into account in the Nordheim calculations.

Notwithstanding the fact that corrections to the shielded resonance integrals were applied, they were insufficient to bridge the gap between lattice analysis and experiment. Consistent use of ENDF/B data underpredicted the reactivity in every case.

## III, DETAILED EXAMINATION OF THE U-238 DISCREPANCY

Very detailed studies of the clean  $H_2^0$  moderated lattices using ENDF/B data were made by J. Hardy of BAPL.<sup>(9,12)</sup> Kemshell<sup>(10)</sup> and others at Winfrith analyzed the problem for a wider range of well thermalized lattices with the data on the UKAEA library. Papers will be presented at the present seminar about these investigations, but some of the most important conclusions will be given in the present review, specially in as far as they relate to the U-238 capture problem.

In 1970 Hardy<sup>(9)</sup> compared shielded resonance integral calculations (based on Nordheim's method) coupled to a more sophisticated procedure below 200 eV, with Monte Carlo estimates. The same data were used throughout. Agreement was good, although there was a bias in that the Monte Carlo values were consistently slightly in excess of the other values (1.5 - 2%). The author referred to the possibility that this trend may be due in part to the way resonance integrals are inferred from the captures.

The main problem arose however in the comparison with experiment. In order to obtain agreement with Hellstrand's measured resonance integrals of

- 7 -

isolated rods, more resonance capture was needed than in order to fit the measured values of  $o_{28}$ , the ratio of epithermal to thermal captures in U-238, in water moderated lattices. The results were interpreted in terms of the smooth capture, i.e., that part of the resonance cross sections which was handled by equivalent smooth cross sections. The principal conclusions are shown in Table 3.

# TABLE 3

## U-238 RESONANCE CAPTURE

Hardy et al (Westinghouse).

	p-wave Dilute Resonance Integral $\int_{c}^{\sigma} \sigma_{c} du (barns)$
Value required to make calculated value of <sup>0</sup> 28 agree with experiment:	0.65
Value required to make the calculated effective resonance integral of isolated rods agree with Hellstrand's experiments:	1.45
ENDF/B-IV Nuclear data (McCrosson)	
Resolved resonance region 0.70 Unresolved resonance region <u>0.84</u>	1.54

The values clearly show the magnitude of the discrepancy and should be compared with the capture integrals of the p-wave resonances which are practically unshielded and are treated usually by equivalent smooth cross sections. McCrosson<sup>(11)</sup> who examined the p-wave resonances in detail in 1973 concluded that the ENDF/B-III p-wave capture resonance integral of 1.83 barns should be reduced by 0.28 barns, but nevertheless the ENDF/B-IV values are clearly greatly in excess of the value required to match the measured lattice values of  $\rho_{28}$ . Of course it is not necessary to look only at the contributions of the p-wave resonances as the cause of the discrepancy, but its magnitude

- 8 -

......

is certainly very large. Subsequent sensitivity studies with ENDF/B-III  $data^{(2)}$  helped to indicate where (at what energies) the reduction of the U-238 capture integral should be made, but did not explain the cause of the discrepancy.

Kemshell<sup>(10)</sup> in 1972 examined the prescription used at Winfrith to evaluate the resonance capture in U-238 in detail. He referred to previous comparisons between the WIMS<sup>(13)</sup> calculations and Monte Carlo values which had been in good agreement. On the other hand, a scaling procedure was required to make the results of calculations based on a detailed tabulation of cross section against energy agree with integral evidence. The scaling is shown in Table 4.

- 9 -

The resonance integral scaling was originally 1.2 barns. By referring to experimental evidence on the relative conversion ratio, the ratio of U-238 captures to U-235 fissions in the lattice relative to the same value in a thermal column, Kemshell suggested modifications to the scaling factor. These depend to some extent on the moderator and are influenced by its scattering cross section in the resonance region. The scaling necessary to make calculations agree with the measured conversion ratio, now amounts to much less than before, but it is still not negligible. The scattering cross sections used at Winfrith are close to the present ENDF/B-IV values.

Kemshell and later Chawla<sup>(14)</sup> drew further conclusions about nuclear data from these studies. In particular they suggested that a harder fission spectrum might be indicated by the measured values of  $\delta^{36}$  which were higher than the WIMS calculations. This ratio of the U-238 to U-235 fissions will clearly increase if the temperature of the U-235 fission spectrum is raised. Chawla used a temperature of 1.43 MeV which is greatly in excess of the current ENDF/B-IV value of 1.323 MeV. He did not consider that the harder fission spectrum would lead to discrepancies between calculated and measured neutron ages in the three principal moderators greatly in excess of the experimental errors.

In addition Chawla sought to account for the low values of  $k_{eff}$  in their  $D_2O$  lattice calculations (even when compared to the other moderators) by changing the very low energy  $\alpha$  values of U-235. A reduction would enhance the  $k_{eff}$  of the most thermalized, i.e. the  $D_2O$  lattices, and have a smaller effect in the  $H_2O$  lattices. The proposed change, which was thought to be reasonable in the light of the available experimental thermal

~ 10 -

nuclear data would extrapolate  $\alpha$  to 0.157, instead of 0.173 in ENDF/B-IV, as the neutron energy tends to zero.

#### IV. POSSIBLE SOURCES OF THE DISCREPANCIES

Previous studies of the discrepancies between thermal reactor lattice calculations and experiments for assemblies containing natural Uranium or fuel of low enrichment have been conducted according to the following pattern. For a given microscopic data set the best theoretical procedures were used in the lattice analysis. The resulting integral lattice parameters were compared with experiment and the discrepancies attributed to the quality of the basic nuclear data.

Recalling the three ingredients which contribute to such comparisons, the question must be asked whether it is certain that the integral experiments and the methods of lattice analysis can be ruled out entirely as contributing factors to the differences that have been observed.

The major area of doubt is clearly the U-238 resonance capture which is strongly influenced by the heavy shielding of the large resonances in the heterogeneous assemblies.

Resonance capture rates have been studied very extensively in the past. Good agreement has frequently been reported between different calculational procedures using the same data base. The tendency of adjusting the data in order to force agreement between theory and experiment was then a natural consequence.

On the other hand it appears desirable to approach the problem at the present stage with an open mind and with full regard to what is currently

- 11 -

ś

available both as regards lattice analysis codes, computer facilities, and experimental data.

Following the procedures previously adopted, one might first of all, question the codes used for the calculations. In order to compare different theoretical approaches it is essential that the comparisons refer to quantities defined in an identical manner. An example of an area of doubt is the resonance integral. Its definition is unambiguous at infinite dilution, but in the presence of heavy shielding the definition must be clarified. It is not certain that the most appropriate definition for an analytical evaluation of the shielded resonance integral for one calculational procedure is also directly applicable to other numerical methods, such as Monte Carlo calculations.

As regards the use of a given data base, further questions arise. The data base should contain an unambiguous procedure for specifying all cross sections at every energy point. Of special interest is the resonance region. The procedure agreed upon to calculate the resonance cross section from the resonance parameters in the data base may be too cumbersome for some methods of calculation of the shielded resonance reaction rates, and simplifications are frequently introduced for each method separately. Even when very detailed resonance profiles are used, questions arise regarding the energy mesh and interpolation procedures used to represent them and the manner in which they have been Doppler broadened. Comparisons between different methods of calculation for the same data bse, such as Monte Carlo versus Integral Transport, certainly merit detailed re-examination, even when close agreement has been reported.

- 12 -

たたちり

Turning to the basic nuclear data, there is the problem of how well the cross sections and resonance parameters are known. In particular one may ask whether the use of a constant radiation width for all resonances is justified, or should be replaced by different values, according to the best measurements, specially in the case of the first few resonances of U-238 which contribute most to the total resonance capture. What accuracy can be expected in the calculated integral parameters in the light of the present uncertainties in the basic data? Is the overprediction of resonance capture of U-238 to the extent reported in the literature consistent with the quality of the basic data? As regards the resonance formalisms used, some fundamental problems also remain. U-238 is an isotope with well separated resonances so that little difficulty is expected from the use of the single bevel Breit-Wigner formulae. On the other hand these formulae appear to be applied, according to current ENDF specifications, in a manner which is inconsistent with certain basic theoretical considerations. In particular negative scattering cross sections and even total cross sections are not excluded even after Doppler broadening. Although these problems occur only over a few narrow energy regions the question remains how well the cross section measurements are fitted by the currently recommended resonance formalisms, specially at energies in the valleys between the large resonance peaks.

The second s

にはしたいないなどになっていたいとうに

Finally, the measured integral lattice parameters might need further study. Confidence limits, allowing for experimental error are generally quoted in the literature, but the measurements might be subject to possible systematic errors which had not been sufficiently well analyzed at the time the experiments were performed. In addition, frequent reference is made to

- 13 -

rather old experiments, in which the measuring techniques were less refined than at present. The selection of the most reliable experimental information on integral parameters from the reported measurements, and a re-examination of sources of systematic errors appear to be of considerable importance.

It may well be that one or more of the problems mentioned can be ruled out as a contributory factor to the existing discrepancies, from studies already reported or those currently in progress. On the other hand the objective of the specification of a single data base, which when properly used will be adequate for the widest range of applications, provides a strong incentive for a fuller understanding of the causes which lead to the current overprediction of U-238 resonance capture in thermal reactor lattices.

#### Monte Carlo Analysis of TRX Lattices with ENDF/B Version 3 Data

J. Hardy, Jr.

#### I. INTRODUCTION

Four TEX water-moderated lattices of slightly enriched uranium rods have been re-analyzed with consistent ENDF/B Version 3 data by means of the full-range Monte Carlo program RECAP (Reference 1). The parameter measurements and the original analysis are described in References 2 and 3.

The following measured lattice parameters were studied: ratio of epithermal-to-thermal  $U^{238}$  captures ( $n^{28}$ ), ratio of epithermal-to-thermal  $U^{235}$  fissions ( $\hbar^{25}$ ), ratio of  $U^{238}$  captures to  $U^{235}$  fissions ( $CR^*$ ), ratio of  $U^{238}$  fissions to  $U^{235}$  fissions ( $\hbar^{28}$ ), and multiplication factor ( $\lambda$ ).

In addition to the base calculations, some studies were done to find sensitivity of the THX lattice parameters to selected variations of cross section data.

Finally, additional experimental evidence is afforded by effective  $U^{238}$  capture integrals for isolated rods. Shielded capture integrals were calculated for  $U^{238}$  metal and oxide rods. These are compared with the measurements of Hellstrand (Reference 4).

### II. LATTICE CALCULATIONS

The TRX fuel rods were of uranium metal (enriched to  $1.3\% U^{235}$ ) clad in aluminum. They were 48 inches long and of 0.387 inch diameter, arranged in hexagonal arrays at four water-to-fuel volume ratios: 1.00, 2.35, 4.02, and 8.11. The two intermediate arrays were full lattices for which measured buckling values were available. The other two arrays were run as inner lattices surrounded by a

~ 18 ~

driver region of TRX high density UO<sub>2</sub> rods. At the center, where parameters were measured, the flux spectra were essentially asymptotic. All these lattices were fully reflected, and their perimeters were made as nearly circular as possible.

In the analysis, Monte Carlo cell calculations were done, with leakage corrections obtained from homogenized, multigroup full-core calculations. The RECAP Monte Carlo program described the lattice cell geometry explicitly and neutrons were followed over the full energy range below 10 MeV.

ENDF/B cross sections were processed with ETOMX and FIAN2, which are Bettis versions of ETOG (Reference 5) and FIANGEII (Reference 6), respectively.

Above 0.625 eV. smooth cross sections, including the inelastic scattering transfer matrix, were described in the 54-group MILC energy structure. Doppler broadened resonance profiles were described at ~25,000 energies. Smooth thermal cross sections were described at 25 energies.

For  $U^{238}$ , all p-wave resonance capture was treated as smooth. The first set of unresolved S-wave resonance parameters was used over the entire unresolved range (4 KeV - 45 KeV), with suitable adjustment of the smooth capture. For  $U^{235}$ , all unresolved resonance absorption was treated as smooth.

Leakage corrections were obtained by means of a multigroup calculation, with cross sections closely matching those of the Monte Carlo. For the two full lattices, the epithermal calculation used MUFT (Reference 7), which treated a homogenized, simply-buckled lattice in the El approximation. An "L-factor" was used to force the  $U^{238}$  capture in the zero-buckling MUFT calculation to match that of RECAF above 0.625 eV. A single L-factor was applied to  $U^{235}$  absorption (fission plus capture) in a similar manner.

Thermally, a DPl calculation was done in 25 energy groups. Thermal disadvantage factors were used to force the zero-buckling thermal reaction rates to match those in the RECAP calculation, and a fast advantage factor was applied similarly to obtain the proper  $U^{2,38}$  fission rate.

Leskage corrections for the two-region lattices were obtained with P3MG (Reference 8), which performed one-dimensional, 54-multigroup calculations in cylinder geometry. The calculations were P3 epithermally and double P-1 thermally. There was one thermal group, with constants condensed from a 25-group calculation for each homogenized core region.

In all cases, leakage correction factors for the RCP-calculated reaction rates were obtained as the ratio of reaction rate in the leaking, homogenized lattice to that in the homogenized lattice with zero-buckling. For the relative reaction rates, the largest such correction was 7% ( on  $\delta^{28}$  in the 2.35/1 lattice) and corrections were usually much less than this. The km values from the Monte Carlo cell calculations were 1.0290, 1.1551, 1.1432, and 1.0099, respectively, for the 1.00/1, 2.35/1, 4.02/1, and 8.11/1 lattices.

Results for the TRX lattices are summarized in Tables 1 and 2 along with the measured parameters. For completeness, Version 2 ENDF/B results are also included. Calculated reaction rates are tabulated in the Appendix.

The following points are noteworthy:

- 1) Both Version 2 and Version 3 produce high  $2^{28}$  and CR<sup>\*</sup> values, indicating ~10% too much epithermal  $U^{238}$  capture in all lattices. As will be seen from the sensitivity studies, this implies about  $1.3 \pm 0.3$  b too much smooth capture integral.
- 2) The increased  $\sigma_f^{236}$  in Version 3 has brought  $s^{26}$  into good agreement with the experiment.  $s^{28}$  is also sensitive to  $\sigma_{1n}^{238}$  and to the  $v^{235}$ fission spectrum. These quantities appear reasonable -- especially the lower  $v^{236}$  inelastic scattering compared to Version 1. The trend

- 20 -

そのうちないというないので、「ないない」

in  $\delta^{28}$  observed in the original analysis (Reference 2) was attributed to too high  $\sigma_{in}^{U^{238}}$  (Version 1 ENDF was used).

- 3) The  $U^{235}$  epithermal fission in Version 3 is from 2% to 9% high compared to experiment ( $\delta^{25}$ ). It averages ~2% higher than Version 2, slightly greater than would be expected from the dilute fission integrals (above 0.625 eV): RI(Version 2) = 266 b and RI(Version 3) = 269 b. Although within the uncertainties, these are somewhat high compared to direct measurements of the  $U^{235}$  fission integral (Reference 9). In particular, the TRX value for the dilute fission integral of  $U^{235}$  is  $276 \pm 11$  b above 0.5 eV, or 260  $\pm 11$  b above 0.625 eV (Reference 10). In any case, Bettis deck 718 with RI = 259 b gives better  $\delta^{25}$  results than either Version 2 or 3. All these cross section sets show a trend toward high values in the tighter lattices.
- 4) Eigenvalues are low by ~1% (.7% to 1.3%). This is about what one expects from the excess  $U^{238}$  capture.

To determine sensitivity of the lattice parameters to selected cross sections, the full core P3MG calculations were repeated for each of the following variations:

- Reduction of U<sup>238</sup> smooth capture integral by 1.0 b in the range 5.5 KeV to 25 KeV.
- Reduction of U<sup>238</sup> smooth capture integral by 1.0 b in the range .625 eV to 6 eV.
- Reduction of U<sup>235</sup> smooth fission integral by 10 b in the range .625 eV to 6 eV.

Results of these variations are shown in Table 3. A reduction of 1.3 b in the low KeV range coupled with 10 b reduction of the  $U^{235}$  fission integral would bring

- 21 -

 $n^{28}$  into line, and eigenvalues as well.  $\delta^{25}$  would be brought into better agreement, although the tendency to calculate high in tight lattices would persist. A reduction of  $U^{238}$  smooth capture in the low eV range (Variation 2), rather than higher up, would help to reduce the drift in  $\delta^{25}$ .

#### III. SHIELDED CAPTURE INTEGRALS

Effective resonance capture integrals for  $U^{238}$  metal and oxide rods were calculated with the RESQ Monte Carlo program (Reference 11). Doppler broadened resonance profiles were described at 24,000 energies from 5 eV to 325 eV. Bettis versions of L. W. Nordheim's ZUT and TUZ were used respectively for the remaining resolved S-wave resonance (up to 4 KeV) and in the unresolved range (up to 45 KeV). Smooth capture integral was added to account for resonance tails gmitted in the resolved range, and to cover the energy ranges 0.5 eV - 5 eV and 45 KeV-10 MeV.

In the interval 200 - 325 eV, both RESQ and ZUT were used and gave good agreement: ZUT-RESQ  $\approx$  .005 b.

Results are shown in Table 4, along with Hellstrand's measured values (Reference 4). The experiment is uncertain to 3.5%. There is good agreement as to slope, but the calculation is high by  $0.75 \pm 0.54$  b on the average.\*

\* Compared to Hellstrand's recommended isolated rod resonance integrals, it averages high by 0.67 b. This is not very different, but overall consistency is less favorable than for Hellstrand's own experiments (see Table 4).

- 22 -

#### IV. CONCLUSIONS

2、1997年、1997年1月1日

Version 3 ENDF/B  $U^{238}$  produces too much capture in TRX lattices by  $1.3 \pm 0.3$  b. Compared to E. Hellstrand's measured isolated rod resonance integrals, it averages high by  $0.75 \pm 0.54$  b. These two comparisons are consistent within the uncertainties. It is felt that the lattice comparison is the more reliable, and that Version 3  $U^{238}$ capture needs to be reduced by slightly more than 1.0 b of smooth capture integral. In addition, a 10 b reduction of the  $U^{235}$  fission integral would considerably improve the  $\delta^{25}$  prediction. In other respects, the Version 3 data work well in these lattices.

## Sn ANALYSIS OF THE TRX METAL LATTICES WITH ENDF/B VERSION III DATA

F. J. Wheeler Aerojet Nuclear Company Idaho Falls, Idaho

## (A) Introduction

Two critical assemblies, designated as thermal-reactor benchmarks TRX-1 and TRX-2 for ENDF/B data testing, were analyzed using the onedimensional S\_-theory code SCAMP\*. The two assemblies were simple lattices of aluminum-clad, uranium-metal fuel rods in triangular arrays with  $H_2O$  as moderator and reflector. The fuel was low-enriched (1.3%  $^{235}U$ ). 0.387-inch in diameter and had an active height of 48 inches. The volume ratio of water to uranium was 2.35 for the TRX-1 lattice and 4.02 for TRX-2. Detailed parameter measurements have been reported (2) for these lattices. Full-core S<sub>n</sub> calculations based on Version III data were performed for these assemblies and the results obtained were compared with the measured values of the multiplication factors (k), the ratio of epithermal-to-thermal neutron capture in  $^{238}U(p^{28})$ , the ratio of epithermal-to-thermal fission in 2350 ( $\delta^{25}$ ), the ratio of 2380 fission to  $2^{35}U$  fission ( $\delta^{28}$ ), and the ratio of capture in  $2^{38}U$  to fission in  $^{235}$ U (CR). Reaction rates were obtained from a central region of the fullcore problems. Multigroup cross sections for the reactor calculation were obtained from  $S_n$  cell calculations with resonance self-shielding calculated using the RABBLE<sup>(3)</sup> treatment. The results of the analyses are generally consistent with results obtained by other investigators. The calculated multiplication factors were 1.8 to 2.6% low for the critical assemblies. This under-estimation of k is thought to be primarily due to the overprediction of the <sup>238</sup>U epithermal neutron capture as is evidenced in the comparison of the calculated values of  $\rho^{28}$  with measured data.

Some of the approximations used in the analyses were investigated including the use of alternate treatments in the resolved energy range, the angular quadrature in the cell calculation, whether the number of thermal groups in the cell calculation (32-group) was enough to elimate spectrum

\*SCAMP, in cylindrical geometry, is a modification of the  $TOPIC^{(1)}$  program.

- 35 -

effects in derivation of thermal constants and the importance of the outer-boundary condition chosen for return of neutrons from the fictitious cylindrical boundary in the cell calculation. For those alternate methods investigated none would significantly affect the conclusions concerning the use of Version III data in low-enriched thermal systems. Effects that were not investigated included the adequacy of the  $P_1$  approximation for the angular scatter distribution, the use of asymptotic thermal spectra at the fuel-reflector interface, the cylindricalization of the outer boundary of the cell and the isotropic assumption for the energy distribution of the source to the thermal groups.

### (B) Summary of Methods and Results

The analyses of the TRX reactor benchmarks essentially consisted of four steps:

- 1. Processing the ENDF/B data into problem-independent library files
- Use of these library files with spectrum and resonance codes to obtain problem-dependent 97-group cross sections for subsequent cell calculations (32 thermal groups)
- 3. Unit cell calculations using  $S_n$  theory
- 4. Homogenized full-core 68-group calculations to obtain final results

For step one, the ENDF/B data were processed using the ETOP $^{(4)}$  and FLANGE II $^{(5)}$  codes.

For step two, quarter-lethargy cross sections in the fast energy range were obtained using modified versions of the PHROG<sup>(6)</sup> and RABBLE codes. The PHROG resolved-resonance treatment was bypassed in favor of the resonance self-shielding as calculated with the RABBLE treatment. The  $INCITE^{(7)}$  code, in the B-l approximation, was used to obtain the 32-group thermal cross section set used in the cell calculations.

For steps three and four,  $S_n$  unit-cell calculations were performed, using the 97-group cross section set, in the  $S_6$ ,  $P_1$  approximation with a semi-isotropic outer boundary condition and a leakage correction (DB<sup>2</sup>) in the fast-energy groups. Subsequent full-core calculations ( $S_6$ ,  $P_1$ ) were performed using cross sections from the cell problem coalesced over space and thermal energy to form a 68-energy group set with one thermal group below .625 eV. Fast and thermal cross sections for the H<sub>2</sub>O reflector were obtained from the PHROG and INCITE spectrum codes assuming asymptotic

- 36 -
water spectra. The comparison of the calculated results with experimental data is given in Table I.

## (C) Details of the Calculational Models

The ETOP code represents an extensive modification of the  $ETOG^{(8)}$  package. Since the changes in ETOP affect the calculational results, these will be briefly outlined.

Problems in data processing originate from two principal sources. The first is incompatibilities between ENDF/B format and the physical approximations incorporated into the spectrum code. The second arises from numerical limitations and inaccuracies over specified energy ranges in ETOP.

ETOP now performs no preliminary processing of ENDF/B unresolved capture, fission and scatter data except for the case where there are several isotopes specified for a single ENDF/B material. In this case, both the resolved and unresolved range parameters are processed at infinite dilution into smooth cross sections for PHROG. At present only a few ENDF/B materials fit into this category. The output smooth data files, in the resolved-resonance range, contain only the averaged data from File 3 plus the contribution from p-wave resonances and the tails of s-wave resonances that do not lie within the energy bounds of the resolved range. This contribution is computed assuming infinite dilution. The original limitations on energy mesh were found to result in serious numerical problems in the calculation of resonance cross sections and elastic-scattering matrices in the resolved-resonance range. The original coding was adequate for version I data when less than 10 or 12 resonances occurred per quarter-lethary group. With the advent of version II data, several isotopes exceeded these safe limits. A large number of resolved p-wave resonances are present in <sup>238</sup>U, for example. A redefinition of the integration intervals was made to reduce numerical error. Mesh problems still exist under the most severe conditions and the only real solution to the problem in these instances is to increase the total number of mesh points in the offending groups. This will require a major modification of the processing code.

The calculation of the elastic scattering matrices in the resolved resonance region is based on a special semi-analytical subroutine  $^{(9)}$  which improves the accuracy of the Legendre matrix elements several orders of magnitude for the case of isotropic scattering in the CM system. This is almost always the intended scattering law in the resolved resonance region.

For this situation, the total Legendre moment of the cross section is known analytically for any order  $\mathfrak{e}^{(9)}$ . For isotopic mass exceeding A=16, only one group downscatter is possible for the 0.25 lethargy-group structure and this downscatter term is easily calculated. The diagonal within-group term is then obtained by subtracting the outscatter term from the total Legendre moment which is obtained analytically. This technique permits a great simplification in the resolved-resonance range since the within-group term presents the greatest numerical difficulty. The extreme mesh requirement for this Legendre convolution is thus avoided entirely where many resonances are involved in the within-group term.. At higher energies, where the scattering is not isotropic, numerical integration of the within-group term is necessary.

The FLANGE II code was used to process thermal data into a 10}-energypoint library below 2.38 eV for use with the INCITE thermal-spectrum code. INC'TE is a program to calculate energy-dependent thermal-neutron spectra and appropriate average-multigroup cross sections using arbitrary scattering kernels. The program employs a normalized Gauss-Seidel iteration technique to solve the energy-dependent integral form of the B-1 approximation to the Boltzman transport equation.

- 38 -

For the treatment in the fast-energy range, a variation of the  $MC^2$  equations for the unresolved range was incorporated into the PHROG II code and the modified RABBLE package to make them completely compatible to the ENDF/B unresolved-range format. Tables of  $J(\theta,\beta)$  were added to treat shielding and temperature effects in unresolved data. Both codes preprocess the unresolved data into self-shielded quarter-lethargy cross sections before performing the final spectrum calculations.

The RABBLE resonance calculation was performed for the cylindricalized cell using an isotropic outer-boundary condition. An interval width of 0.001 was used to determine the lethargy mesh in the transport calculation. At each energy point, the  $^{238}$ U cross sections were determined using the sum of the Breit-Wigner single-level cross sections for the three nearest (in energy) resonances. In the case of  $^{235}$ U, cross sections were summed over the 20 nearest resonance levels at each energy point. The smoothed background cross sections and the cross sections for the non-resonance isotopes in the cell were the quarter-lethargy values output by the ETOP code.

The 97-group, SCAMP-cell calculations were performed assuming 12 spatial intervals in the fuel, 25 in the water and l each in the gap and cladding. The  $S_6$  (6 intervals on the azimuthal-angle halfspace) approximation was used with 4 Gauss-quadrature points on the polar-angle halfspace. Scatter was assumed to be linearly-anisotropic and a leakage term w.s applied in the fast groups through a DB<sup>2</sup> term. Upscatter was treated to 0.876 eV and molecular binding effects in water were treated to 2.38 eV. At the outer boundary of the cell the return current was treated using a semi-isotropic reflection albedo which assumes mirror return in the polar angle and isotropic return in the azimuthal angle.

The SCAMP code has an option to compute average cross sections coalesced over energy and space. This option was used to obtain cross sections for the cell, homogenized over all regions and collapsed over the thermal groups to 0.625 eV forming a 68-group cross section set for input to the full-core calculations.

For TRX-1, a SCAMP zero-leakage cell calculation was performed and compared to the full-core calculation to determine the magnitude of the leakage correction for each of the parameters of interest. The results, shown in Table II, indicate that the leakage effect is small for the central reaction-rate ratios and only about 15% for the multiplication factor.

TABLE II TRX-1 LEAKAGE EFFECT

## (D) Alternate Resolved Resonance Treatments

Since resonance shielding is very important in these lattices, calculations were made to compare results obtained using alternate treatments in the resolved-resonance range. The PHROG II code was used to investigate the following effects.

- The comparison of results obtained using the approximations in the PHROG II resonance treatment and the RABBLE treatment.
- 2. The errors resulting from the use of 3 neighboring levels in  $^{2\,3\,8}\text{U}$  and 20 neighboring levels in  $^{2\,3\,5}\text{U}$  when computing pointwise cross sections.
- 3. Comparison of PHROG II results with those obtained using pointwise  $^{235}$ U cross sections computed by the ACSAP<sup>(10)</sup> code using both the Breit-Wigner single-level formulism (SL) and the Reich-Kore formalism (RM).

The major modifications that form the PHROG II package were in the treatment of the resonance shielding where the numerical accuracy was improved. Also, the code was made compatible with ENDF/B data. The original PHROG coding treated resonance absorption by means of a direct numerical solution, formulated by Nordheim,<sup>(11)</sup> to the neutron collision density equations. A serious limitation of the ETOP-PHROG package was that the elastic-scattering matrices were pre-computed by ETOP. The compound-elastic contribution from the resolved and unresolved range was calculated at infinite dilution

- 40 -

precluding the possibility of shielding the compound elastic resonance data. This is a very important effect for  $^{238}$ U in low-enriched thermal systems. Added to the library file for those isotopes with resonance parameters is a file containing the background P<sub>0</sub> and P<sub>1</sub> scatter matrix computed from the data on the ENDF/B version III tape. This background matrix allows the generation of a problem-dependent self-shielded scatter matrix which represents an improvement over the PHROG representation of the scatter matrix as constant data.

Other improvements in the resolved resonance calculation are (1) the inclusion of overlap effects due to neighboring resonances of an individual isotope and (2) a user-specified option allowing the selection of either the asymptotic 1/E flux or the depressed lump flux in the definition of the quarter-lethargy group cross section output from the resonance routines.

The physical model employed in the PHROG II resolved-resonance calculations assumes a 1/E slowing down flux above the upper-energy cutoff of the resolved energy range. The geometry may be homogeneous or a lump surrounded by an external moderator. The geometry of the lump may be either slab, cylindrical, or spherical, and up to three scattering nuclides (in addition to the absorber atom) may be present, providing a slowingdown source within the absorber lump. The flux in the range of integration is computed assuming a slowing-down density determined by the flux above the range of integration and a 1/E flux in the external moderator, if present. A correction to the magnitude of the source from the external moderator is required in a tight lattice because of mutual "shadowing" of the absorber lumps. This shadowing is approximately taken into account by a redefinition of the escape probability which makes use of the Dancoff-Ginsburg correction.

The general procedure used in obtaining the solution over each range of integration is as follows. The energy interval over which the range of integration is chosen is determined by points midway in energy between the resonance peak of the level associated with the interval and its adjacent neighbors. For the highest energy resonance, the upper cutoff of the interval is determined by the upper cutoff of the resolved-energy range; and for the lowest-energy resonance, the lower cutoff of the resolvedenergy range or 0.414 eV, whichever is lower. For this range, a lethargy width is chosen which limits the point-to-point cross section variation due

...

to Doppler breadening (see reference 11). At each mesh point across this interval, Doppler-broadened absorption, fission, and scatter cross sections are computed assuming the Breit-Wigner single-level formulation and a Maxwellian distribution of absorber velocities. The cross sections at each point are accumulated for N neighboring resonances where N is input by the user. Then, beginning at the uppermost energy of the range,  $E_1$ , the pointwise flux in the absorber medium is computed from the scatter source within the medium and the external source from the moderator, if any. The contribution to each interaction cross section is then accumulated for each PHROG II group which intersects the integration interval, by means of trapezoidal integration.

Multigroup (67 fast, ] thermal) SCAMP-cell calculations were performed using regionwise cross sections generated entirely by PHROG II with the depressed lump flux used in the denominator of the equations defining the average cross sections in the resolved range. Comparison with results using the RABBLE treatment showed no significant difference for the TRX-1 lattice (the leakage-corrected k was increased by ~0.04%). Thus, for this lattice, the effects due to interference between  $^{235}$ U and  $^{238}$ U and the asymptotic spectra assumption in the moderator are apparently small.

The effect of the number of resonance levels used to define the pointwise resolved cross sections was investigated for the TRX-1 cell. The effect due to increasing the number of neighboring levels from 3 to 5 for  $^{238}$ U was to increase the shielded resonance integral by 0.017 barn, a 0.1% change. The effect due to increasing the number of neighbors from 20 to 128 (all levels) in  $^{235}$ U was to increase the fission integral by nearly 1.6 barns, a 0.6% change. Thus, the calculated value of  $^{25}$  would increase from the reported value of 0.1019 to a value of 0.1025, and an increase in k of  $^{-0.01\%}$  would result had all the neighboring levels in  $^{235}$ U been included in the definition of the pointwise cross sections.

The  $^{235}$ U self-shielding in these lattices is small and therefore the multilevel effect is correspondingly small. However, calculations were run to determine this effect in TRX-1 and to compare results using the ACSAP code to determine the pointwise cross sections in the resolved range. Single-level and multi-level (RM) cross sections for  $^{235}$ U were generated with ACSAP using all levels to define the cross sections at each energy point. The multi-level parameters used were taken from an evaluation by Smith. The cross sections were input to the PHROG II code using a special option and a shielding calculation was performed for each case.

- 42 -

Even though the smooth file is self-shielded, the use of ACSAP single-level cross sections resulted in a fission integral 2.7 barns higher than obtained from a comparable PHROG II calculation, thus ACSAP SL cross sections would predict about a 1% higher  $\delta^{25}$ .

When the results of the multi-level calculation were compared to single-level results no significant effects were seen in integral results although groupwise cross sections varied by as much as 6%.

# (E) Summary of Sensitivity Studies in the Thermal Range

The effects due to some of the approximations employed in the thermal energy range were investigated for the TRX-1 cell. Briefly these were:

- 1. An S<sub>10</sub> cell calculation was performed. The change in computed reaction rates, compared to the S<sub>6</sub> calculation, was very small (~0.02%).
- 2. A cell calculation was performed employing an isotropic outerboundary condition. The computed fuel disadvantage factor was  $^{\circ}0.07\%$  higher than that obtained using the semi-isotropic albedo.
- 3. The assumption that the 32-group structure was adequate to assure problem-independency of the group cross sections was investigated by means of an INCITE problem in which space and energy self-shielding factors were applied by region and group. Subsequent SCAMP cell calculations, using cross sections from this INCITE case, showed changes in the reaction rates "0.1% indicating some problem dependency, however final results would be affected only slightly.

#### The Current UK Position on Uranium-238 Resonance Capture

J.R. Askew AEE, Winfrith April 1975

## Abstract

The paper reviews the large body of integral evidence on l'ranium-238 resonance capture accumulated since 1966, when attention was first drawn to a discrepancy between integral evidence and calculated results based upon differential data. The experiments cover many reactor types, laboratories and measurement techniques, and include studies of isotopic composition of discharged fuel. 「日本」の「日本のないで、ないない」「「「「日本」」

Server Street Street

and the second of the second 
variable and

、その中心は東京などの合体の東京などのなどのないなどのないなどのないないないであったので、「「「「「「「「「「「」」」」」

It is shown that the discrepancy still exists, although changes in other data (particularly Uranium-235 resonance capture) have reduced the size of the deduced discrepancy to 4-8%. (Note added in proof: As the ENDF B IV data appears to give a higher resonance integral than the 'basic' differential data chosen here, the correction required would be greater).

It is argued that the differences are within the uncertainties of measurement of parameters for the low lying resonances which dominate thermal reactor calculations. These were originally believed to be more accurate because it was thought acceptable to assume capture widths invariant and to average them over many resonances. Once this is not permitted the differences become explicable.

#### The Current UK Position on U-238 Resonance Capture

## J R Askey

# 1. Introduction

At the 1966 ANS Topical Meeting on Reactor Physics in the Resonance and Thermal regions two papers from the UK (1, 2) drew attention to the discrepancies between prediction and observation in lattice experiments which were ascribed to errors in the data for resonance capture in Uranium-238.

It appeared that a 10% reduction in resonance capture was required to give agreement with both reaction rate and reactivity for the range of light water and graphite moderated lattices studied, which included both metal and oxide fuels.

Since that time more experimental data have become available and more systematic analyses performed. Some changes in data for other nuclides especially for Uranium-235 - will affect the results obtained. This paper sets out to describe the position now reached in this area, which is that the discrepancy still exists but is smaller than originally estimated, lying in the range 4-8%.

## 2 Differential Data

Table 1 shows the resonance parameters for the resolved region used in the original studies, and compares them with data due to Nordheim (3). These were shown to give very similar results.

To investigate the hypothesis that an independent compilation of resonance parameters might significantly modify the nature of an inferred correction to resonance integrals, a recent re-evaluation of GENEX cross-sections based on parameters chosen by James (12) has been evaluated in the WIMS context. The new parameters for the resolved region which now extends to 5 keV are listed in Appendix 2. The intention in this compilation was to reproduce the  $U^{2,0}$ capture cross-sections at higher energies (is at energies of a few keV) which have been inferred from Fast Reactor integral data studies  $(1^3)$ , and which over an appropriate energy range would be approximately 10% lower than an evaluation by Sowerby, Patrick and Mather  $(1^{44})$ . Below 5 keV the recent measurements of Rahn et al  $(1^{5})$  have been used which have been argumented with p-wave and small s-wave resonances generated randomly from suitable distributions. In the unresolved region, above 5 keV, both s- and p-wave neutron widths were then adjusted to give the desired average capture cross-section. The adjustments were all within the known statistical uncertainty for such a generating process. For all resonances for which the capture width Ty had not been measured, a value of 23.0 meV was assumed. This includes the important 6.7 eV resonance. The other mean parameters were taken to be:

Mean resonance spacing for s-wave resonance  $(\overline{D}) = 22.5 \text{ eV}$ s-wave strength function S<sub>0</sub> = 0.93 x 10<sup>-4</sup>

p-wave strength function S<sub>1</sub> = 1.8 x 10<sup>-4</sup>

The previous WIMS  $0^{238}$  group cross-sections are compared with values obtained from this compilation, and also with the Sowerby et al energy variation in Fig 2. On average, the James' parameters have given about % reduction in the keV region. The SDR homogeneous resonance integrals for a temperature of SOOK obtained from the new GENEX Lape are compared in Table 2 with the standard uncorrected resonance integrals available in the WIMS library.

Table 2

#### Comparison of Resonance Integrals (0.55 eV-2 MeV) Obtained from James Compilation with Basic WIMS Library Data

(Note temperature 900°K)

<b>O</b> p	James RI	WIMS RI
barns	barns	barns
15-53	13.95	14.52
31-49	18.44	19.20
53-40	23.07	24.05
65-34	25.22	26.30
146-2	36.70	38.36
261-3	48.89	50.87
00	266.51	273.41

It will be seen that this evaluation gives a 4% reduction in resonance integral over the range of practical interest in power reactors, at the expense of a reduction in the infinitely dilute resonance integral which seems unlikely to be consistent with integral data. None the less, it is encouraging that some link between fast and thermal reactor requirements for data adjustment can be seen, even if the proposed route is tenuous by virtue of the dominant effect of the 5.7 eV resonance in the thermal system.

The opithermal data for Vranium-235 originally used were due to Brookes(16) and resulted in a cepture/fission ratio of 0.64 above 0.5 eV. Subsequent integral studies (4) showed that this was in error, and the data currently in use correspond to a value of 0.5. The point is discussed in Reference 5.

Epithermal cross-sections for moderating materials have also changed, as is illustrated in Table 3.

#### Table 3

Cross-Section of Moderating Materials in the Resolved Resonance Region ( $\sigma_{\rm s},~{\rm Barns})$ 

	Hydrogen	Deuterium	Carbon
Abkew 2 (1966)	20.50	3.40	4.70
Tayers 5 (1967)	20.00		
Chawla 6 (1972)	20.30	3.35	4.75

It will be seen that these changes are not large compared to the discrepancies under consideration.

## 3. Calculational Models

The integral comparisons reported here have all been carried out using the lattice codo WIMS (7). This is described in References 7 and 8 with some minor improvements to the resonance treatment detailed in Reference 5. The WIMS scheme is based upon a 69-group data library and allows space/energy solutions in various degrees of complexity including full collision probability modelling of doubly heterogeneous cluster geometries. Because of its direct relevance to the problem of Uranium-238 resonance capture we shall sketch briefly the model used for this purpose. おおこう きょうかい

1.47

CT WALLED TO THE A

The energy range from 4eV to 9.118 keV is divided into 15 groups of irregular width, so arranged that resonances of the most important muclides are either central or uniformly spaced within them. Group data are tabulated as partial resonance integrals for a mixture of the resonance absorber with Hydrogen as a function of the effective potential cross-section of the mixture per absorbing atom (Sp) and temperature T.

For application to simple model problems, such as regular pin-lattices an equivalent value of Up is determined taking into account the effective contribution of intermediate mass nuclides mixed with the absorber (including (xygen) and a geometric term depending upon the mean chord length of the pin, together with Dancoff and Bell factors. The former term representing pin-toin interactions, the latter allowing for departures from the black limit in integrating the collision probability equations over energy.

The model permits first order representation of the effects of overlapping of resonances of different nuclides on a statistical basis.

The partial resonance integrals are converted to cross-section using an internally consistent model for the flux depression caused by the resonances, so that used consistently in a few group spatial solution the correct reactions are preserved.

A small correction is made to group removal cross-sections to allow for the depletion of the slowing down density due to the resonance absorption. The model is valid for cluster geometries including those with more than one moderating material.

The basic features of the model were validated by extensive comparisons of each step against more detailed methods. The overall process was demonstrated to have a precision of better than 7% of total reconnance captures for a range of systems when compared to detailed Wonte Carlo calculations using the identical cross-sections used to generate the WIMS library for a range of moderators, fuel mixtures and geometries as shown in Table 4 below, reproduced from Reference 9.

More recently an alternativo method of determining effective reasonance data, based upon sub-group arguments, has been developed and tested (10). The advantages of this is its ability to model rather general geometries, including parts of pins (for example, distinguishing the outward facing skin in an edge pin where the Plutonium build-up will be greater). This model is regarded as very promising for engineering applications, but post-dates the results reported here.

## 4. Comparisons with Hellstrand Correlation

Although comparison with measurements of relative conversion ratio in lattice configurations probably provide the most reliable evidence of the adequacy of resonance data for  $U^{2,0}$ , further checks are provided by Hellstand's integral experiments. These experiments have been designed to provide a direct measure of resonance integral (is resonance capture resulting from a 1/E-source) and thus the resulting correlation should in principle be appropriate for direct comparison with the WIMS library.

In practice some difficulties in detail arise in making the comparison. Hellstrand's own experimental results have been modified  $\binom{11}{11}$  to take into account the results from other integral experiments. The resulting best fit formulae for the energy range 0.55 eV - 2.0 Mev are:

**U-Metal** Rods

U-Oxide

-----

$$RI = 5.60 + 26.3 \sqrt{S/M}$$

We note that Hellstrand's original interpretation of his measurements on metal rods was subsequently adjusted upwards by about 41% in the light of later results.

The resonance integrals in the WIMS library were deduced from SDR calculations of resonance captures by using the basic formula derived in Ref. (7),

$$\Sigma_{a}^{s} = \frac{\frac{N_{8} I_{8}^{s}}{r_{s} - \frac{N_{8} I_{8}^{s}}{\Sigma_{p}}}$$

where  $\sum_{n}^{\infty} S_{n}$  is the group effective absorption cross-section,  $18_{23}^{\infty}$  and  $N_8$ the group shielded resonance integral and number density of  $0_{23}^{23}$  respectively,  $\sum_{n}^{\infty}$  is the potential scattering cross-section of  $0_{23}^{-23}$  with admixed hydrogen in the SDR calculation, and  $T_{g}$  the group lethargy width. This is a general approximation appropriate to all types of moderators, which is also invoked within WIMS to relate effective cross-sections to the tabulated resonance integrals. Thus cancelling effects are likely to occur if any error is associated with deducing resonance integrals from the SDR calculations using it. On the other head, for the purposes of a comparison with Hellstrand's correlations, it is questionable whether the classical exponential formula

$$p = 1 + c = \exp\left(-\frac{1}{\frac{1}{526}}\right)$$

~ 51 -

which is exact for mixtures of hydrogen and an infinite mass absorber should be preferred. In practice it is found that for large values of p the two formulae give the same numerical values. The difference becomes just noticeable at low p values, thus at  $\sigma_p$  = 16 barns the use of the exponential form reduces the inferred resonance integral by 0.3 barns. The results discussed in the following comparison all refer to use of the WINS equation.

Hellstrand's correlation being given in terms of S/M, the surface to mass ratio, it is necessary to relate this ratio to the  $\sigma_p$  basis of the WIMS library. In order to relate  $\sigma_p$  to S/M we are obliged to use the WIMS equivalence principle.

$$\sigma_{p} = \frac{a}{\frac{N_{0}}{1}} + \sum_{i} \lambda_{i} \sigma_{pi}$$

where a is the Bell factor, N<sub>2</sub> is the number density of  $U^{238}$  atoms,  $\overline{I}$  is the mean chord of the rod  $(2r_0)$ , <sup>o</sup>pi is the potential scattering cross-section of an admixed element i in the fuel, and  $\lambda i$  is the Goldstein-Cohen factor for intermediate resonance effects. The currently recommended values of  $\lambda$  and <sup>o</sup>p for  $U^{230}$  in the WIMS library are 0.2 and 10.636 barns, while for oxygen the appropriate values (10) are 0.94 and 3.7 barns. The summation terms in Eq. (6) give 2.13 barns for U-metal and 9.08 barns for U-oxide. The Bell factor 'a' is itself a weak function of <sup>o</sup>p, and should be evaluated using the univeral curve given in Ref. 8. The appropriate relationship with S/M obtained is

$$\sigma_{p} = \frac{eA}{4A_{v}} S/M + \sum_{i} \lambda_{i} \sigma_{pi}$$

where A, is Avogadro's number and A the molecular weight.

The high-energy spectrum which is pertinent to Hellstrand's experiments is in some doubt. Simulation of the lattice conditions in the measurements by a WINS calculation  $\binom{2}{2}$  suggests that the spectrum cut-off lies in the range 100-500 keV. Various calculated spectrum corrections have been made to the sets of measurements underlying the best fit correlations in order to give the proper  $\frac{1}{E}$  -integral up to 2.0 MeV (see Ref. (11)). The uncertainty in resonance integrals arising from the correction appears to be about - 2% and the total uncertainty from all causes is quoted by Hellstrand as - 3.5%.

The results of the comparison are shown in Table 5.

The ranges over which the correlations were actually fitted are marked '\_\_\_\_\_' in the table. In the central portion of these ranges we see that the WIMS resonance integrals are about 3% higher than the U-oxide correlation and about 4% lower than the U-metal correlation. There appears to be about 5% discrepancy

"An exact value for Op for  $U^{233}$  is not necessary since provided the other aspects of the equivalence theorem are valid, this parameter mercly serves as a link to the appropriate SDR homogeneous calculation.

between the two correlations, although this is probably within the claimed accuracies for the correlations (the consistency would be improved by returning to Hellstrand's older interpretation of his U-metal experiments). Since for the application to power reactor lattices we are concorned with oxide fuels, we see that the conclusions deduced from relative conversion ratio measurements are in excellent agreement with the appropriate Hellstrand correlation.

#### Table 5

#### Comparison of WIMS Resonance Integrals (-0.7b Corrected Set) with Hellstrand Correlations

	WTHE	Oxide Rods			Hetal Rods

Comparisons have also been made between the WIMS prediction of temperature broadening and the inferred values of  $\beta$  from hot experiments, where  $\beta$  is defined by

 $RI(T) - \xi = (RI(T_0) - \xi) [1 + \beta (\sqrt{T} - \sqrt{T_0})]$ 

S is the "1/v" portion of the resonance integral above 0.55 eV, and T and T are expressed in K. The results are given in Table 6. Over the ranges of the measurements the agreement between WINS and experimental  $\beta$ -values is very good, with WINS showing a tendency to a small over-prediction.

Table 6 Comparison of  $\beta$  x  $10^2$  for U-Oxide and U-Metal Rods

- 54 -

The original comparison of WIMS data against Hellstrand results, reported in Reference <sup>2</sup> was for a metal sample, and showed good agreement with basic resonance parameters (unmodified data). We see that this is consistent with our data here. The inconsistency appears to arise between the metal and oxide results, despite the demonstrated capability of the WIMS model to reproduce the change from metal to oxide consistently by comparison with Monte Carlo results, and to fit integral experiments on both systems with a single data modification.

We conclude that the Hellstrand "world-best" correlations for oxide are consistent with our other integral observation, whilst those for metal differ by an amount of the same order as the 3.5% uncertainty ascribed to them.

#### 5. Evidence from Zero Power Measurements

#### 5.1 Reactivity measurements

t

Chawla has summarized the evidence obtained for a wide range of systems analysed using WIMS. We reproduce below the reactivity results for various sets of these when using the basic WIMS data reduced by approximately 5%. (The actual model used is described in Appendix I, and corresponds to a uniform 0.1 barn reduction in cross-section. It corresponds more closely to a reduction of 0.7 barns in resonance integral at all rod sizes than to a constant percentage). 深いの 言語 特

\* hydrogen scattering cross-section normalised to 20.0 barns

+ hydrogen scattering cross-section normalised to 20.3 barns

It will be seen that the 0.1 barn (approx 4%) corrected set of data which reproduces the change in reactivity with pitch gives consistently good results, although a rather larger correction would be even better:

The same set of data have been applied to HTR lattices where, as has been noted, there is double heterogeneity, the sperical fuel kernel being packed into cylindrical or annular pins. Tables 9 and 10 show that both the effect of variations in kernel size and packing density and the effect of temperature changes up to  $400^{\circ}$ C are well reproduced, although again the reduction of 0.1 barn (approximately 2-3% of resonance integral in these lattices) is not sufficient to give a best fit.

For SGHW cluster lattices the coolant inside the cluster of pins may be varied. A typical sequence going from air-filled to water-filled cluster, via an intermediate state of mixture of heavy and light water in roughly equal proportions to give the equivalent of operating water density, is reported by Chawla (6) and shown below using the 0.1 b reduced cross-section set.

Table 11

Relative Conversion Ratio for SG3 Lattices

Coolant	Relative Conve	rsion Ratio
	Calculated	Heasured
Air	1.978	1.987 ± .017
Mixture	1.872	1.894 ± .019
Vater	1.694	1.707 ± .018

These results are breadly in line with the Euch wider study undertaken by Kenshell (17) in which he includes a range of Canadian cluster lattices ranging from 7 to 28 pins having air, heavy water and organic coolants. The conclusion of thisstudy was that the originally proposed 0.2 barn reduction in the resonance cross-section was a slight over-estimate of the required correction.

Over all systems it was concluded that the smaller reduction of 0.1 barns in cross-section (~0.7b in resonance integral) gave the best fit to experiment.

## 6. Comparisons with Tactopic Composition Data from Power Reactors

The WINS  $U^{235}$  data with the approximate 4% correction of resonance integrals (ID 3238.5) is normally the preferred option used in design calculations for LWR's. Halsall has completed an LWR-WIMS evaluation of the isotoric depletion of fuel discharged from the Yankee-Rowe reactor which gives good agreement with the measured  $Pu/U^{235}$  discharge composition. The comparison between measurement and prediction for both the 4% and 8% corrected data is shown in Fig 1, which indicates a preference for the smaller correction. Also shown in Fig 1 are the LASER results which indicate that the combination of resonance cross-sections and shielding factors used in the MUFT section of LASER are equivalent to a resonance integral some 8% lower than the WIMS 4% corrected data.

Further evidence on the preference on resonance integrals is obtained from WIMS analysis of the isotopic depletion of the Canadian NPD and Winfrith SGHW Reactors. Although the moderation by heavy water in these reactors could lead to some systematic differences relative to observations in LWR's, the results should still be useful iron the standpoint of establishing absoluto resonance integral data. The NPD results associated with % corrected  $U^{235}$  data

"The broad assumption has been made that the principal difference between WIMS and LASER characteristics lies in the conversion ratio, since both codes obtain guite good agreement on the composition of the plutonium produced.

Figure 2. Comparison of WIMS Library Cross-Sections with Recent Evaluations.

- 64 -

which also shows the results associated with use of the 4% option. We sae that with the latter the plutonium production is too nigh by about 2%. The equivalent results for SGHWR were discussed in Ref (10) and are given in Table 5, which indicates that the conversion ratio associated with the 4% modification is slightly too high by approximately 0.6%. Thus we find that although the 4% corrected  $U^{2/3}$  data essentially satisfied both the RCR's under cold conditions and the isotopic depletion in Yankee and SGHWR, the conversion ratio implied by the Pu/U ratio in the NFD reactor requires a somewhat larger correction than 4%. This lack of consistency in results remains to be recolved at the present time, although it is possible that systematic errors in the measurements could be contributing to the difficulty. It is noticeable that the preference towards % corrected data becomes stronger as the power reactor spectrum softens, which might be taken to imply an error in the  $U^{2/3}$  thermal crosssection. However the large range of spectra in cold lattices for which good agreement has been obtained on RCR measurements militates against an error in thermal cross-section. On balance the 4% correction to resonance integrals is preferred for all types of WIMS calculations.

#### 7. Effect of Variations in Conversion Ratio on Cycle Length

Calculations on typical light water reactor lattices show that changes in resonance capture have a rather similar effect on cycle length and plutonium discharge for both FWR and BWR systems. Typically our 0.1 barn cross-section reduction (4% in resonance integral) will increase cycle length by 3.7% and reduce Plutonium concentration at a given discharge irradiation (30,000 HWD/Te) by 3.5%.

#### 8. Summary and Conclusions

Since the original discussion of discrepancies between differential and integral data a large number of additional experiments have been studied, especial attention being paid to the determination of relative conversion ratio. Additional information on isotopic composition has become available for different types of reactor.

Changes to other data - especially the epithermal capture integral in Uranium<sup>235</sup>- have reduced the magnitude of the discrepancy observed, from 10-15% in resonance integral down to 4-6% which is now seen to cover the majority of observations.

The Hellstrand correlations for resonance integral have an associated uncertainty of -3.5% which is rather high for our purpose. The oxide data arc, however, in good agreement with the position deduced here, whilst the metal data are slightly outside the range preferred.

In the differential data field it has become accepted that the resonance capture width may vary from resonance to resonance. Once it is not acceptable to average measurements over a large number of resonances the accuracy of determination is no longer adequate for thermal reactor applications. The dominant effect of the lowest (5.7 eV) reconance - which is much the most difficult to measure - gives expected overall precisions only of the order of e&c, and it is therefore no longer appropriate to regard the difference between integral and differential data as a discrepancy. The one remaining problem in this area is that most proposed routes to change the resonance integral by varying capture widths change the infinitely dilute integral by an unacceptable amount, and it would be encouraging to have an alternative model for the changes.

We therefore conclude that an adjusted set of resonance data for Uranium<sup>238</sup>, used in conjunction with up to date data for other nuclides is capable of predicting observed results on a wide range of reactor designs. The majority of results fall within -  $\approx$  consistent with a standard deviation of the order of 1% - 1.5%.

(Note added in proof. It appears that ENDF B III and IV data lead to resonance integrals 0.5 barns higher than the 'uncorrected' values used in this paper, and thus the discrepancy would be greater using this data source.)

.

# APPENDIX 1

	Appi	coximat	.e	influence	on	Resonance	Integra	1		
from	uniform	shift	in	different	tinl	Cross-Sec	tions (	J.	R.	Askew)

We assume that the constant shift in cross-section to be introduced is  $\Delta\sigma_{r}$  then the resonance integral shifts from

$$\tau = \int \frac{\sigma_{a} \sigma_{p}}{\sigma_{A} + \sigma_{p}} \frac{dE}{E}$$

to

$$I^{*} = \int \frac{(\sigma_{a} + \Delta \sigma) \sigma_{p}}{(\sigma_{a} + \Delta \sigma + \sigma_{p})} \frac{d\Sigma}{E}$$
$$\frac{\sigma_{p}}{\sigma_{p} + \Delta \sigma} \left\{ I(\sigma_{p} + \Delta \sigma) + \Delta \sigma (\tau - \frac{I(\sigma_{p} + \Delta \sigma)}{\sigma_{p} + \Delta \sigma}) \right\}$$

Now if we take  $I \simeq I_{OB}^{\sigma}$ , we obtain

•

$$\Delta I = I' - I = \frac{\sigma_p I_0 \sqrt{\sigma_p + \Delta \sigma}}{\sigma_p + \Delta \sigma} \left\{ 1 - \frac{\Delta \sigma}{\sigma_p + \Delta \sigma} \right\}$$
$$- I_0 \sqrt{\sigma_p} + \frac{\Delta \sigma \sigma_p}{\sigma + \Delta \sigma} \tau$$

If  $\frac{\Delta \sigma}{\sigma_p}$  is small, then expanding gives

$$\Delta I = \sqrt{\sigma_p} I_o \left\{ 1 - \frac{3\Delta\sigma}{2\sigma_p} - 1 \right\} + \Delta\sigma \tau \left( 1 - \frac{\Delta\sigma}{\sigma_p} \right)$$

Hence

$$\frac{\Delta I}{\tau} = \Delta \sigma \left(1 - \frac{3I(\sigma_p)}{2\sigma_p \tau}\right)$$

#### ANALYSIS OF THE "FOUR-FUEL" EXPERIMENTS USING HAMMER

#### bу

# D.S. Craig

The object of this paper is to draw your attention to measurements which have been made by A. Okazaki et.al at Chalk River on a series of 37 element clusters using different fuels— $UO_2$ , UC, U-Si-Al, and U. The cluster geometry was identical for all fuels, the moderator was  $D_2O$  and measurements were made using four different coolants—air,  $D_2O$ , H<sub>2</sub>O, and HB4O (an organic). The geometry of the cluster is shown in Figure 1. Although it is very complicated, the calculation of reactivity for the air and  $D_2O$  lattices depends primarily on the reaction rates in U235 and U238. The absorptions in other materials is small—worth about 50 mk of which 40 mk is in the aluminum pressure and calandria tubes, With H<sub>2</sub>O and HB4O coolants, the parasitic absorption increases by about 70 mk. Of interest to the seminar on U238 resonance capture are measurements which have been made of the ratio of captures in U238 to fissions in U235.

I have used the Savannah River Laboratory cell code HAMMER and the ENDF/B-IV data for U235 and U238 to calculate parameters for these lattices. However, before presenting the results, I would like to draw your attention to Tables I and II giving the results I have obtained for the thermal test lattices TRX and MIT, as well as an AECL lattice ZEEP. The latter lattice uses natural uranium rods, 32.57 mm in diameter, clad in aluminum and with a D<sub>2</sub>O moderator so that the geometry is particularly simple. It is important to see how well these calculations handle these simple lattices before considering the more complicated 37-element clusters.

- 72 -

The HAMMER values of  $k_{eff}$  are low by 9 to 17 mk. In general, the Savannah River Laboratory code RAHAB gives better values. This improvement arises from a better calculation of  $6^{28}$ , the ratio of fission in U238 to that in U235. Values of this ratio were not available from these particular RAHAB runs. However, in Table III, I compare RAHAB and HAMMER calculations for a 7-element cluster. The results are seen to be similar except that RAHAB gives a higher value of  $6^{28}$ . The calculated value of the conversion ratio is high for ZEEP by 2 percent—for the other lattices it is within twice the estimated error. However the calculated value of  $\rho^{28}$ , the ratio of epithermal to thermal captures in U238 are all 6-10 percent high.

I have not attempted to calculate the "Four-Fuel" lattices using the cluster geometry. Instead, the calculations were made with the fuel pins being represented by concentric tubes of fuel separated by coolant. Thus, geometric effects may contribute to the trend indicated in Table IV where the ratio of the calculated to experimental values of the conversion ratio are given for these lattices where measurements were available. The experimental values are estimated to be accurate to 1 percent. Also given are  $k_{\rm eff}$  and the estimated values of  $k_{\rm eff}$  which would be obtained if the resonance integral of U238 were adjusted to make the calculated value of the conversion ratio agree with the experimental value. Because of a 0.1 m<sup>-2</sup> uncertainty in the buckling measurements and a 1 percent uncertainty in the conversion ratio, this estimated value of  $k_{\rm eff}$  is uncertain by about 7 mk.

In general, it appears that errors in the calculated conversion rations (all high) correlate well with errors in  $k_{\rm eff}$  indicating that the absorption rate in U238 is being constantly overestimated for all the fuels, coolants and lattice pitches considered, when using the ENDF/B-IV data files.

- 73 -

On Figure 2 are shown the calculated values of  $k_{eff}$  for the complete 32 lattices. Measurements were made at pitches of 245 mm and 310 mm. The results are better for the 310 mm pitch. They also appear better for the H<sub>2</sub>O and HB40 coolants. There is also a general trend to get worse as the density of the fuel increases.

Thus the general conclusion is that where the absorption rate in U238 is relatively high (tight pitch, poor coolant moderation, high density fuel) the errors in our estimates become larger.

# EFFECTIVE U238 RESONANCE INTEGRALS IN CLUSTERS OF NATURAL URANIUM FUELPINS DERIVED FROM CRNL LATTICE MEASUREMENTS

## J. Griffiths, AECL

## INTRODUCTION

Lattice parameters fast fission ratio, initial conversion ratio, thermal neutron fine structure, thermal neutron spectrum parameters and buckling, have been measured at CRNL for a wide range of natural uranium lattices. The lattices consisted of regular arrays of fuel clusters, containing natural Umetal,  $UO_2$ , UC,  $U_3Si/Al$ cooled by  $D_2O$ , AIR, organic liquid and in a few cases  $H_2O$ , in  $D_2O$ moderator, for a wide range of lattice pitches.

U238 resonance absorption rates in these lattices can be derived from the lattice parameters. These absorption rates have been related to effective U238 resonance integrals by means of the EPITHET  $^{(1)}$  computer code.

## METHOD

Using the cross-sections given in table la and assuming values for the cross-section ratios given in table lb, it is fairly evident that the lattice parameters can be manipulated to give resonance absorption rates in U238.

The cross-sections given in table la are those used by the AECL lattice code LATRF?. The cross-section ratios of table lb are obtained from representative cases run on the LATREP code. To determine resonance integrals from the resonance absorption rates obtained from the lattice parameters, use has been made of the EPITHET code. This is a multigroup, multiannular region code which can be operated in several modes. The mode chosen for this work is a coarse group

į

- 81 -

## Table la

## Cross-Sections\*

U235 2200m/s absorption	679.9 barns
U235 2200m/s fission	579.5 barns
U238 2200m/s absorption	2.72 barns
U238 effective fast capture	0.2446 barns
U238 effective fast fission	0.551 barns
U235 Y thermal	2.43
U235 Y fast	2.80
U238 Y fast	2.801

\* The excessive number of decimal places given for some values does not imply high accuracy, but reproduces values given in certain CRNL lattice codes.

÷

A substant of the last of the substance of

mode with U238 absorption represented by resonance integrals. In all 33 groups span the energy range 10 Mev to 1.4 ev. Previous work using EPITHET has established how the total U238 resonance integral should be distributed among the energy groups comprising the resonance region. Using this energy split, an iterative series of calculation : using EPITHET can be performed. In these iterative calculations, the total resonance integral is changed until the calculated resonance absorptions agree closely with the values derived from the measured lattice parameters.

/\* error analysis was performed for the resonance absorption rates, which included the experimental errors and the errors assigned to the assumed ratios of table lb. The error in the resonance integral due to these error accumulations was estimated by performing the resonance integral evaluation three times, once for the nominal absorption rate and once for each of the nominal value plus and minus the accumulated errors.

#### RESULTS

In these well moderated lattices, the effective resonance integral is not expected to vary with lattice pitch. The results derived bear out this expectation. Where results are available for more than one lattice pitch, the resonance integrals have been averaged to obtain a mean value and at the same time the standard deviation about this mean value has also been obtained. In table 2, effective resonance integrals averaged over lattice pitch are given for each lattice. Cluster average values, values for each ring of fuel pins, along with the error derived from the experimental errors and the standard deviation about the mean value over the pitch, can be found in that table. Quite large uncertainties are generated from the experimental errors, typically 20-30%. However, the results are much more consistent than these errors would indicate. Standard deviations about the mean over several pitches being typically 3 to 4%. A well known source of experimental effective resonance integrals is the experimental data of Hellstrand. In figure 1 both the effective resonance integrals in UO<sub>2</sub> derived here and the UO<sub>2</sub> values of Hellstrand are plotted against  $\sqrt{\frac{S}{M}}$ . Here S is an

effective fuel surface area and M the mass of fuel. 5 is derived from a CRNL recipe and no doubt contributes to the scatter evident in figure 1. It is apparent that the values derived here are in good agreement with those measured by Hellstrand. Some confidence, therefore, can be placed in these results for both the UO, fuel and the other fuel materials.

# Adjustment of the effective <sup>238</sup>U resonance integral to force agreement with integral data

By Malte Edenius, AB ATOMENERGI, Studsvik, SWEDEN

## 1. Introduction

and the state of the second

5 M 10 0 N

As is well known even the most advanced cell codes fail to prodict the reactivity for instance of LWR lattices correctly without some adjustments to group cross section data generated from basic nuclear data files. In particular it has been found necessary to lower the  $^{238}$ U capture cross section calculated from basic data in the ENDF/B libraries to get results consistent with integral data from lattice measurements. The purpose of the present note is to use the resonance treatment in an advanced cell code (CASCO [1]) developed at AB Atomenergi to calculate the resonance absorption in isolated fuel rods surrounded by a large moderating region and to normalize the calculated resonance integrals to experimentally determined expressions for the resonance integral. The latter have been taken from the review article in [2]. Different forms for a correction to the effective  $^{238}$ U resonance integral are suggested to force agreement with the experimental values and some examples are given of how such corrections improve the lattice calculations.

- 87 -

## 2. Calculational method

Effective cross sections in the resonance region are obtained using an equivalence theorem which relates the heterogeneous problem to an equivalent homogeneous problem. Expressing the fuel-to-fuel collision probability,  $P_{ff}$ , as a sum of rationals

$$P_{ff} = x \sum_{n}^{\beta} \frac{\beta_{n}}{x + \alpha_{n}} \quad \text{with} \quad \sum_{n}^{\beta} \beta_{n} = 1$$
 (1)

 $(x = 4V_f \Sigma_f / S_f, V_f)$  is the fuel volume,  $S_f$  the fuel surface and  $\Sigma_f$  the total cross section.  $u_n$  and  $\theta_n$  are fitting parameters.)

one obtains the resonance integr of the heterogeneous system, RI, as a sum of homogeneous integrals,  $RI_{\rm h}$ 

$$RI = \sum_{n} \beta_{n} RI_{h}(\sigma_{p} + \alpha_{n} \sigma_{e})$$
(2)

 $\sigma_{p}$  is the fuel potential scattering cross section per absorber atom and  $\sigma_{e} = S_{f}^{/4}V_{f}^{N}$ , N being the absorber number density. The equivalence theorem is based on the narrow resonance approximation, but by a suitable modification of  $\sigma_{p}$  it is also valid in the intermediate resonance approximation.

The CASCO code uses a rational approximation for the fuel self collision probability suggested by Carlvik [3]

$$P_{ff} = \frac{2x}{x+2} - \frac{x}{x+3}$$
(3)

which is more accurate than approximations based on a single rational.

The resonance energy region (4 eV - 9 keV) was in the calculations divided into 13 energy groups and groupwise tabulations of  $RI_h$  as function of temperature and background cross section were used in the equivalence

- 88 -

relation. The  $^{2.98}$ U data in the CASCO library is generated from the ENDF/B-111 resonance data using the Studsvik code system ETOS, SPENG and DORIX [4].

The Doppler broadened line shape was obtained using the v- and v-functions, i.e. a Maxwellian velocity distribution was assumed for the absorbing nuclei. This is a good approximation for U-metal, but in  $UO_2$  due to crystalline binding the uranium atoms vibrate with an average kinetic energy larger than that in a free gas state. This is approximately accounted for in CASC? by use of an effective Doppler temperature,  $T_{eff}$ , which is higher than the true temperature, T, of the fuel [5]

$$T_{eff} = \frac{3}{2} \dot{v}_D \int_0^1 x^3 \coth\left(\frac{x\dot{v}}{2T}\right) dx$$
 (4)

where the Debye temperature,  $\theta_{\rm D}$ , in UO, is put equal to 620 K [6].

## 3. Comparison with measured resonance integrals

Calculated resonance integrals and their temperature dependence were compared with experimental integrals and Doppler coefficients for  $UO_2$  rods and U-metal rods with two different radii. The smaller  $UO_2$  radius is typical for a BWR-rod and the larger one gives background cross sections corresponding to a Dancoff factor of 0.5.

The expressions recommended in [2] for the room temperature integrals are

RI = 5.60 + 26.3 $\sqrt{S/M}$	for UO2	(5)
RI = 4.25 + 26.8 $\sqrt{S/M}$	for U-metal	(5)

S/M is the surface to mass ratio of the fuel expressed in  $cm^2/gram$ .

- 89 -

The experimental temperature dependence is described by

$$RI(T) \sim \delta = \left[ RI(T_{o}) - \delta \right] \left[ 1 + \delta \left( \sqrt{T} - \sqrt{T_{o}} \right) \right]$$
(6)

where T and T<sub>o</sub> are expressed in K and 5 is the 1/v-contribution to RI above 0.55 eV. The experimental value of the temperature coefficient,  $\beta$ , which was assumed to be independent of temperature was taken from [7]

$$f = (0.58 + 0.5 \text{ S/M}) \cdot 10^{-2} \qquad \text{for UO}_2$$

$$f = (0.51 + 0.5 \text{ S/M}) \cdot 10^2 \qquad \text{for U-metal}$$
(7)

The experimental results in Table I were obtained by use of expressions (5) and (7). The experimental uncertainties are about 4 % in the resonance integrals and about 10 % in the Doppler coefficients.

Calculated resonance integrals and Doppler coefficients are compared with experimental values in the first column of Table 2. The resonance integral comparison is done for T = 300 K. The comparison of Doppler coefficients shows the average deviation in the interval 300-1000 K.

The calculated resonance integrals are 7-10 % larger than the measured values, whereas the Doppler coefficients agree within the experimental uncertainty. The use of T<sub>eff</sub> given by Eq. (4) reduces the Doppler coefficient by about 20 % at room temperature in the UO<sub>2</sub> cases and by a few per cent at high temperature, giving an average correction of about 10 % in the interval 300-1000 K.

## 4. Adjustment of the resonance integral

In order to force agreement with integral deta, the  $^{238}$ U cross sections in the energy region 4 eV - 9 keV were reduced in the calculations. Three different types of corrections were tested, viz.

- 90 -

Corr. 1 
$$\Delta \sigma_{a} = -0.26 \text{ b}$$
  
" 2  $\Delta \sigma_{a} = -0.26 [1+0.007(\sqrt{T}-\sqrt{300})] \text{ b}$   
" 3  $\Delta RI = -0.09 \text{ RI}$ 

The relation between  $\Delta \sigma_a$  and RI in energy group g is obtained by differentiating

$$\sigma_{a,g} \approx \frac{RI_{g}}{\Omega U_{g}}$$

$$\Delta U_{g} = \frac{RI_{g}}{\sigma_{p,g}}$$
(8)

i.e.

$$\frac{\Delta RI_{g}}{\Delta U_{g}} = \Delta \sigma_{a} \left[ 1 - \frac{RI_{g}}{\Delta U_{g} \cdot \sigma_{p,g}} \right]^{2}$$
(9)

Correction 1 has the advantage that the unshielded resonance integral is reduced by only 2.0 b which is within the experimental uncertainty. Using this correction the calculated resonance integral at room temperature is within 1 % of the experimental value for the UO, rods and within about 3 % for the U-metal rods. The calculated Doppler coefficient is, however, increased by 10-16 % so that the temperature dependence in the U-metal rods is overestimated. In order to preserve the temperature dependence of the uncorrected resonance integral correction 2 was tested. This correction is identical with correction 1 at 300 K but does not change the  $\sqrt{T}$ -dependence of the resonance integral. A drawback is, however, that although the Doppler coefficient for the whole resonance energy region is not changed, ARI /AT in individual energy groups will be erroneous. For example, in a group without any resonance, where  $\Delta RI_{g}/\Delta T$  should be equal to zero, one obtains  $\Delta RI_{AT} < 0$  . Correction 3 also leaves the Doppler coefficient unchanged but gives a value of the unshielded resonance integral which lies outside the experimental uncertainty.

## 5. Criticality in LWR-lattices

Table 3 shows calculated values of  $k_{eff}$  for some uniform pin cell lattices in the KRITZ-facility at Studsvik. In the UO<sub>2</sub> cases the reactivity is underpredicted by 1.4-1.9 % using the unmodified - ""U data. Using corrected data the reactivity is increased by about 2 % giving a slightly overestimated  $k_{eff}$ . The change is about the same for the three tested types of corrections. The table illustrates the results obtained with correction 1. The influence of the resonance absorption on reactivity is much smaller in the overmoderated PuO<sub>2</sub> case. In this lattice  $k_{eff}$  was increased by 0.7 % when the resonance integral was reduced. We note that the spread in predicted reactivities is much smaller after than before the correction of the  $e^{-i\pi t}$  data. Similar results are obtained for a number of different lattices studied in KRITZ.

## 6. Conclusions

Using the methods described in the paper it is shown that calculated shielded resonance integrals for  $2^{38}$ U with cross sections from ENDF/B-III are 7-10 % larger than measured resonance integrals and calculations using uncorrected  $2^{38}$ U data underpredict the reactivity in LWR-lattices. By normalizing the calculated effective resonance integrals to measured integrals for isolated fuel rods calculated reactivities in much better agreement with experimental results were obtained for a large number of different lattices. The three tested types of corrections give about the same results in typical LWR-lattices.

Using correction 1 the calculated Doppler coefficient is about 10-15 % larger than what is obtained with the other two suggested corrections or with unmodified data. However, all calculated Doppler coefficients except that for the U-metal rods with correction 1 lie within the experimental uncertainties.

# PRECISE MEASUREMENT AND CALCULATION OF <sup>238</sup>U NEUTRON TRANSMISSIONS\* D. K. Olsen, G. de Saussure, E. G. Silver, and R. B. Perez

Oak Ridge National Laboratory Oak Ridge, Tennessee 37830

We have measured above 0.5 eV the total neutron cross section of  $^{238}$ U in precise transmission experiments and have compared the results with ENDF/B-IV. Special emphasis was placed on measuring transmissions through thick samples in order to obtain accurate total cross sections in the potential-resonance interference regions between resonances. These total cross sections are important in computing shielded resonance capture integrals. It has been observed<sup>1</sup> that such shielded integrals are overestimated by ENDF/B-IV.

The neutron energies were determined by time of flight along a 41.68 m flight path at ORELA. The detector was a 7.62-cm diameter, 1.0-mm thick Li-glass disk viewed edge-on by two RCA-7585 phototubes. At 20 m from the neutron source isotopically-enriched, room-temperature <sup>238</sup>U disks with inverse thicknesses of 1/n = 5405, 1603, 807, 266, 80.7, 19.2, and 5.7 barns/atom were alternated in and out of the beam with 10 minute cycles. At least four separate transmission measurements with various combinations of Cd, In, Co, Al, Mn, and Au beam filters were made for each sample thickness. Blackened resonances from these filters aided in estimating the background levels both as a function of energy and sample thickness. In the resolved resonance region, the experimental resolution was limited by the neutron slowing down time in the H<sub>2</sub>0 moderator and was approximately given by  $\Delta E/E \approx .0012$ . After

~ 95 -

subtracting the background (1.0 to 2.0%) and deadtime-correcting the sample-in and sample-out time-of-flight spectra, the resulting transmissions for each sample thickness were combined. The transmissions through the three thickest samples are compared in Figs. 1 to 3 with resolution-broadened transmissions calculated from the ENDF/B-IV total cross section which was Doppler broadened to 300°K.

In particular, Fig. ] shows the experimental transmission up to 4000 eV through the .254-cm-thick sample of  $^{238}$ U (1/n = 80.7 barns/atom). The smooth curve is the corresponding transmission from ENDF/B-IV radii, resonance parameters, and single-level Briet-Wigner, SLBW, formalism. Below 1000 eV no major discrepancies are observed between the calculated and measured transmission dips of the strong s-wave resonances. A few disagreements exist between the measured and calculated transmission dips of the weak, low-energy, p-wave resonances. Figure 2 shows the transmission through the 1.08-cm-thick sample (19.2 barns/atom). Above 1000 eV the measured transmission dips are either equal to or larger than those from ENDF/B-IV indicating that a resonance-by-resonance analysis of these data would perhaps give neutron widths equal to or larger than those contained in ENDF/B-IV. Figure 3 shows the transmission through the thickest sample (3.62 cm). These data are very sensitive to the cross section between resonances and the s-wave interference minima. Between 2000 and 4000 eV the ENDF/B-IV total cross section reproduces the measured transmission reasonably well. Between 40 and 2000 eV ENDF/B-IV consistantly underestimates the total cross section giving a transmission larger than that which is measured experimentally. In fact, in some s-wave minima ENDF/B-IV gives a total cross section which is negative resulting in a transmission greater than unity.

- 96 -

These discrepancies are perhaps clearer in Fig. 4, which shows the experimental transmission from 50 to 300 eV thr 1gh the thickest sample. The upper smooth curve, as before, is the corresponding transmission calculated from the ENDF/B-IV radii, resonance parameters, and SLEW formalism. The lower smooth curve shows the transmission as obtained from a more exact calculation of the total cross section using:

- (1) the Reich-Moore formalism;<sup>2</sup>
- (2) the resonance parameters and scattering radius (.9185  $\times$   $10^{-12}$  cm) from ENDF/B-IV; and
- (3) the "ladder approximation" (levels with uniform spacings and widths) to make an end effect correction for resonances outside the resolved resonance region, that is, a "ladder" from -∞ to 0.0 eV and from 4.0 keV to +∞.

This more exact calculation of the total cross section reproduces the measured transmission much better and does not yield negative cross sections. In particular, the inclusion of multilevel effects with the Reich-Moore formalism<sup>2</sup> removes the negative cross sections in the s-wave minima, but does not significantly reduce the overall discrepancy between resonances. This discrepancy is removed by the end-effect correction which includes levels outside the resolved resonance region with the "ladder approximation."

The increase in the total cross section between resonances as required by the experimental transmissions will reduce strongly self-shielded capture resonance integrals. In particular, Table I compares such integrals for various dilutions,  $\sigma_0$ , calculated with the SLBW approach of ENDF/B-IV and the Reich-Moore formalism with the ladder approximation. The limits

- 97 -

of integration are taken from 100 to 680 eV. In this energy region the smooth background file (file #3 of ENDF/B-IV) is zero. The last column of Table I is the ratio of the third column to the second column. In particular, the capture integral from 100 to 680 eV shielded down to 10.0 barns decreases by 4.4% when the Reich-Moore formalism with the ladder approximation is used in place of ENDF/B-IV procedures. A more complete description of the experimental aspects of this work will be given in an Oak Ridge National Laboratory internal report.

THE  $^{238}U(n,\gamma)$  CROSS SECTION ABOVE THE RESONANCE REGION

# R. B. Perez, R. R. Spencer, and G. de Saussure Oak Ridge National Laboratory Oak Ridge, Tennessee 37830

Recent <sup>238</sup>U capture cross section measurements quote uncertainties in the 5% to 10% range, but often discrepancies between data are larger, indicating that some sources of error have not been properly identified.

Before 1970 all the measurements of the <sup>238</sup>U capture cross section but one, that of Moxon,<sup>1</sup> had been done with nearly monoenergetic neutron sources and most of those measurements had been done relative to the <sup>235</sup>U fission cross section. The interpretation of such measurements is complicated not only because of the structure in the <sup>235</sup>U fission cross section, but also because the <sup>238</sup>U capture cross section has considerable structure which needs to be measured more accurately and evaluated.

In Fig. 1 we compare the 1970 evaluation of Davey<sup>2</sup> to ENDF B-IV in the region below 100 keV. We also show some typical experimental data. Data obtained before 1970 are represented by full figures, recent data by open figures. Some error flags have been omitted so as not to overcrowd the figure. Data derived from ratios of the <sup>236</sup>U capture to the <sup>235</sup>U fission or absorption cross sections have been recomputed using ENDF B-IV values of the <sup>235</sup>U cross sections.

As can be seen on Fig. 1, there are large uncertainties in the data and discrepancies between measurements. ENDF/B-IV is lower than Davey's evaluation partly because the <sup>238</sup>U capture cross section is correlated to the <sup>235</sup>U fission cross section by the ratio measurements, and the ENDF/B-IV value of the latter cross section is lower than that evaluated by Davey.<sup>3</sup>

Research sponsored by the Energy Research and Development Administration under contract with the Union Carbide Corporation.

- 103 -

The recent measurement of Panitkin <u>et al</u>.<sup>4</sup> extends from 24 to 145 keV and was done with nearly monoenergetic neutrons from the <sup>7</sup>Li(p,n) reaction, and relative to the <sup>235</sup>U fission cross section. The point of Block et al.<sup>5</sup> was obtained at 24.3 keV with an iron-filtered beam, and relative to Au. As we have already mentioned, these data must be interpreted in the light of the structure in the <sup>235</sup>U fission and <sup>235</sup>U and Au capture cross sections. The data of Chelnokov <u>et al</u>.<sup>6</sup> were also obtained relative to the <sup>235</sup>U fission cross section, using a lead slowing down spectrometer.

Only four measurements done with a white neutron source and the timeof-flight technique have been reported before 1974. The data of Moxon<sup>1</sup> extend to 200 keV and have uncertainties ranging from 4% to 8%; the data of Fricke <u>et al.</u><sup>7,21</sup> extend to 1 MeV with errors of the order of 12%; the data of de Saussure <u>et al.</u><sup>8</sup> extend to 100 keV, the errors range from 5% to 10%; finally the measurement of Spencer and Kappeler<sup>9</sup> covers the range 20 to 550 keV, but the results are still preliminary. The three first measurements were done with a Linac, were normalized by the saturated resonance technique at 6.7 eV, and were relative to the <sup>10</sup>B(n, $\alpha$ ) or <sup>10</sup>B(n, $\alpha\gamma$ ) reaction up to 80 keV. The results of these three measurements averaged over decimal intervals up to 100 keV are compared in Fig. 2 where we also show.ENDF/B-IV.

Figure 2 shows that there are discrepancies between the results of the three measurements. Those discrepancies are substantially larger than the known uncertainties and do not show a consistent pattern: below

- 104 -

ことでいうないないないないないないないないないである

1

5 keV the ORELA data agree within 6% with those of Moxon but are 25% larger than those of Fricke <u>et al.</u>; above 50 keV the ORELA data and those of Fricke <u>et al</u>. agree to within 3% but are 20% larger than those of Moxon!

In Fig. 3 we compare the 1970 evaluation of the <sup>238</sup>U capture cross section above 100 keV by Davey<sup>7</sup> with the recent evaluation by Sowerby <u>et al</u>.<sup>10</sup> and with ENDF/B-IV.<sup>11</sup> Some typical experimental data are also shown, the data older than 1970 as full figures, the recent data as open figures; data derived from ratio measurements with respect to the <sup>235</sup>U fission cross section were recomputed using the ENDF/B-IV value of the <sup>235</sup>U cross section. The considerable differences in the three evaluations below 2 MeV reflect the considerable uncertainty in the cross section; the agreement between the evaluations above 2 MeV reflects the lack of measurements in that region!

The errors in the <sup>238</sup>U capture cross section are strongly correlated to those in the <sup>235</sup>U fission cross section, not only by the precise measurements of the ratio of those two cross sections, such as that of Poenitz,<sup>12</sup> but also because some authors have measured the absolute <sup>238</sup>U capture cross section and <sup>235</sup>U fission cross section using the same techniques and the same detectors to determine the incident neutron flux. If an evaluator favors a given set of data for the <sup>235</sup>U fission cross section, it is logical that he should also give much weight to the <sup>238</sup>U capture cross section obtained in the same installation, by a similar technique.

In the region from .1 to .5 MeV the data of Menlove and Poenitz<sup>13</sup> are about 17% lower than those of Barry, Bunce and White.<sup>14</sup> Davey gave

- 105 -

much weight to the data of White<sup>15</sup> in his evaluation of the <sup>235</sup>U fission cross section.<sup>3</sup> Since the data of White and the data of Barry <u>et al</u>. were obtained "from the same flux," Davey also weighted the data of Barry <u>et al</u>. in his <sup>238</sup>U capture cross section evaluation,<sup>2</sup> and he renormalized the values of Menlove and Poenitz to agree better with those of Barry <u>et al</u>. Sowerby <u>et al</u>.<sup>10</sup> performed a simultaneous evaluation of several cross sections including <sup>238</sup>U capture and <sup>235</sup>U fission. For this evaluation they choose to treat the data of Barry <u>et al</u>. as ratio measurements relative to the fission data of White. ENDF/B-IV choose to give more weight to recent data which are mostly independent of the <sup>235</sup>U fission cross section: the data of Fricke <u>et al</u>.,<sup>7</sup> of Ryves <u>et al</u>.<sup>16</sup> and the preliminary data of Pearlstein and Moxon.<sup>17</sup>

Sowerby et al.<sup>10</sup> estimate that the  $^{238}$ U capture cross section is known to 7% from .1 to 1 MeV: in the same range ENDF/B-IV<sup>11</sup> estimates an uncertainty of 5%. We think that these estimates are very optimistic, considering that there is more than 20% discrepancy around 1 MeV between the 1973 evaluation of Sowerby et al. and ENDF/B-IV!

The lack of agreement in the value and shape of the neutron capture cross section of  $^{238}$ U below 100 keV among the three linac experiments suggests further measurements. Spencer and Kappeler<sup>9</sup> performed a measurement with the pulsed 3-MV Van de Graaff at Karlsruhe, making use of the  $^{7}$ Li(p,n)<sup>7</sup>Be reaction. The idea was to provide a degree of experimental independence and in that way resolve previous difficulties. For example the Van de Graaff technique has no interfering gamma flash and, due to the very fast timing employed, background considerations are different and less complex. The detector utilized in this experiment was an 800\_liter liquid scintillator tank. Both a standard gold capture

- 106 -

and This is the second second
sample and a <sup>235</sup>U fission chamber were employed as flux monitors in an attempt to obtain a partially independent verification of the measured capture yield shape. Hence this measurement should be considered as a shape decommination only.

The data were normalized to a value of 200 mb for the interval 90 to 100 keV. This is the value reported in an evaluation of Sowerby et al.<sup>10</sup> Below 200 keV the gold cross section of Kompe<sup>18</sup> was used to derive a <sup>238</sup>U capture cross section (see Table I). Above 200 keV a recent measurement of Le Rigoleur et al.<sup>19</sup> was used which agrees well with the data of Kompe<sup>18</sup> in the region of overlap. Recent gold measurements of Macklin <u>et al.</u><sup>20</sup> which are normalized by means of the "black resonance" technique at 4.9 eV are in agreement (± 3%) with the Kompe and Le Rigoleur results, and therefore add justification to the use of these particular sets of data.

Table II shows the results of the  $^{235}$ U fission chamber reference data. To obtain the  $^{238}$ U(n, $\gamma$ ) cross section shape the  $^{235}$ U fission cross section evaluation of Sowerby et al.<sup>10</sup> was used.

The estimated error of around 11% is mainly due to the normalization value. The shape is believed to be accurate within 5%. Below 100 keV the shapes of the  $^{238}$ U capture cross section derived from both the gold reference cross section and the  $^{235}$ U fission cross section as reference are in excellent agreement with the results of de Saussure et al.<sup>8</sup> and in fair agreement with Moxon's<sup>1</sup> data. Below 50 keV there are substantial shape deviations with the measurement of Friesenhahn et al.<sup>21</sup>

- 107 -

A similar neutron source, the  ${}^{7}Li(p,n){}^{7}Be$  reaction with incident protons from the Argonne tandem-dynamitron, was used by Poenitz<sup>22</sup> for his measurement of the  ${}^{238}U$  capture cross section. The capture gammaray detector was a 1300 liter tank filled with a liquid scintillator. The Grey Neutron Detector, or some times the Black Neutron Detector or a  ${}^{6}Li$ -glass detector were used as neutron monitors. Similar to the Spencer and Kappeler  ${}^{9}$  experiment, the ratio  ${}^{238}U$  to  ${}^{197}Au$  capture cross section ratio was measured. Then absolute measurements of the  ${}^{197}Au$ capture were performed to obtain the  ${}^{238}U(n,\gamma)$  cross section. The results of Poenitz measurements are in good agreement with the activation results of Ryves. ${}^{16}$  They differ in shape from the results of Friesenhahn <u>et al.</u> ${}^{7,21}$  and although about 7% lower than the ORELA<sup>8</sup> results, there is in general good shape agreement with the ORELA measurement.

The latest measurement available is due to Le Rigoleur <u>et al</u>.<sup>23</sup> who used a total energy weighting technique in conjunction with the capture gamma-ray detector, Macklin and Gibbons.<sup>24</sup> The neutron flux was measured with a  ${}^{10}$ B NaI(TR) detector with a  ${}^{6}$ Li-glass scintillator. The results were averaged over 10 keV energy intervals below 100 keV and in 20 keV intervals above 100 keV. Some of the data are shown in Fig. 4. Below 100 keV Le Rigoleur's results are 6% to 8% below those of ORELA,<sup>8</sup> between 10% and 20% higher than Moxon's data and agree ±5% with the results of Friesenhahn <u>et al</u>.<sup>21</sup> Between 120 and 250 keV, they fall lower than any previous measurement in this energy range. For example, when compared with Ryves<sup>16</sup> activation measurements, one observes that Le Rigoleur's measured points lie lower by 15% than Ryves results at 160 keV and by 6% at 238 keV. But there is better agreement above 400 keV.

なるのないので、「ないない」で、「ない」ので、「ない」ので、

 $\mathbf{i}^{*}$ 

We now turn our attention to the considerable experimental evidence of long range fluctuations in the  $^{238}$ U capture cross section shown by the recent high resolution experiments. This structure is illustrated in Fig. 5, from a recent paper by Spencer and Kappeler.<sup>9</sup> In that figure the authors have compared the shape of their preliminary data to that obtained in the ORELA measurement.<sup>8</sup> Both sets of data have been averaged over intervals of .5 to 1 keV width. The KFK data in this figure have been arbitrarily normalized, so that the agreement in magnitude is not significant. We have added to the figure the ENDF/B-IV evaluation.<sup>11</sup> Below 45 keV the evaluations is represented by statistical parameters so that some structure is implied, but clearly the details of this structure are important and need to be represented more directly by the evaluation.

To test whether or not the observed long-range fluctuations in capture represent departures from the compound nuclear model, the Wald-Wolfowitz<sup>25</sup> runs and correlation tests were applied to Monte-Carlo generated <sup>238</sup>U capture cross sections and to the ORELA<sup>8</sup> measurements. Both the mock-up cross sections, computed on the basis of the compound nucleus model, and the actual data were averaged in energy intervals ranging from 600 eV up to 3 keV. The measured and mocked-up capture data averaged over 1200-eV intervals are shown in Fig. 6, together with the fits to the s-wave and p-wave strength functions.

The results of the Wald-Wolfowitz tests (Table 3) show with a high confidence limit that the fluctuations in the  $^{238}$ U(n, $\gamma$ ) data cannot be accounted for by the compound nucleus model. Possible explanations for the presence of the observed intermediate structure are based on the Strutinsky double-humped fission barrier or the existence of "door-way"

- 109 -

states in the entrance reaction channels or perhaps a combination of both. Theoretical considerations <sup>25</sup> lead to the concept of modulated strength functions due to local enhancements of the partial reaction widths. The ORELA data, averaged over 1200 eV, were fitted with the modulated strength function model. The result of this procedure is shown in Fig. 7. In this figure the solid line represents the intermediate structure. When this structure was removed from the data, the Wald-Wolfowitz tests showed that the remaining structure behaved randomly.

#### Conclusions.

A number of measurements of the  $^{238}$ U(n, $_{\gamma}$ ) cross section above the resonance region have been completed in the past few years. In the keV region these measurements suggest a considerable amount of intermediate structure.

An idea of the present status of affairs is given by inspection of Fig. 8. The low resolution shape of the <sup>238</sup>U capture seems to be reaching a "consistent" status with the exception of the Friesenhahn <u>et</u> <u>al</u>.<sup>7,21</sup> measurement, and two points (at round 35 and 85 keV) in the results of Moxon. Large differences in normalization are still present. However the results seem to settle above the ENDF/B-IV evaluation between the high ORELA data and the low Moxon data set. This trend will help to obtain better agreement between the calculated and measured value of the dilute capture resonance integral. The presence of intermediate structure has several implications:

 (a) Effects on the validity of activation measurements and "spot" mormalization procedures of the capture cross section, especially at neutron energies such as 24 and 30 keV, where large fluctuations exist.

- 110 -

and a substanting and a

(b) One may question the validity of the present statistical representation of the unresolved region. For example, corresponding to the 24-ke? iron window, there is a large enhancement of the 238U capture cross section. Hence, the actual detailed behavior of the intermediate structure should be included in the representation of the  $238U(n,\gamma)$  cross section. At ORNL we are presently in the process of testing the effect of these fluctuations in fast reactor calculations.

In summary taking into account that fast breeders are mostly lots of iron with a sprinkle of plutonium and a heavy blanket of  $^{238}$ U for breeding, the neutron capture of this important material has to be known better than at least 3%. It is then clear that considerably more work will be needed to achieve this goal.

#### ACKNOWLEDGMENT

٠.-

We would like to thank C. Le Rigoleur and W. P. Poenitz for their communications on their most recent work on the  $^{238}U(n,\gamma)$  cross section measurements.

## EVALUATION OF 238U CROSS SECTIONS FOR ENDF/B-IV

F. J. McCrosson

Savannah River Laboratory E. I. du Pont de Nemours & Co. Aiken, South Carolina 29801

### INTRODUCTION

In this paper, the evaluation of the <sup>238</sup>U cross sections below 4 keV for ENDF/B-IV will be discussed. These cross sections were reevaluated because the Data Testing Subcommittee of the Cross Section Evaluation Working Group (CSEWG) found ENDF/B-III did not accurately predict several important parameters for thermal systems. For example, in both D<sub>2</sub>O- and H<sub>2</sub>O-moderated lattices of natural or slightly enriched uranium rods, k<sub>eff</sub> is underpredicted using Version III by 1.5%. This underprediction has been attributed to a 10% overprediction of <sup>238</sup>U epithermal neutron capture.<sup>1</sup>

These thermal data testing results have raised questions concerning the ENDF/B-III cross sections because the calculational methods used in the analysis of the benchmark experiments generally have been considered adequate. Several possible deficiencies in the Version III <sup>236</sup>U cross sections have been

- 122 -

proposed; e.g., the existence of systematic errors or spurious p-wave resonances could give rise to excessive <sup>238</sup>U neutron capture.

This paper discusses the thermal cross sections; the epithermal cross sections, particularly the s- and p-wave resonances and the background cross sections; and the impact of the new ENDF/B-IV evaluations on thermal lattice calculations.

### DISCUSSION

Thermal Cross Sections (E < 1.0 eV)

The thermal region in the evaluation spans energies below 1 eV. The cross sections in this region are tabulated in File 3. The evaluation for the thermal cross sections followed the procedures used in the Version II and Version III evaluations; i.e., the evaluation used a multi-level Breit-Wigner formulation that incorporated the first mine low-energy s-wave resonances plus an appropriate complement of bound levels.<sup>2</sup> The Version IV thermal evaluation differs from ENDF/B-III in two respects: First, the differential capture cross sections were normalized to 2.70 barns at 0.0253 eV, rather than to 2.72 barns. Second, the thermal breakpoint was lowered from 5 to 1 eV to avoid possible problems in accounting for resonance self-shielding for the 6.67-eV resonance.

The lower capture cross sections are in better agreement with the 1969 measurements of Hunt et al.<sup>3</sup> of 2.69  $\pm$ 0.03 barns and improve prediction of criticality in the thermal benchmark

- 123 -

lattices. They are, however, in poorer agreement with the measurements of Bigham et al.,<sup>4</sup> which yielded a value of 2.721  $\pm 0.016$  barns.

In addition, the thermal cross sections should include the contributions associated with subthreshold fission as measured by Block et al.,<sup>5</sup> but these were inadvertently omitted from File 3. The cross section for fission at 0.0253 eV should be  $1.918 \times 10^{-6}$  barn.<sup>5</sup>

Epithermal Cross Sections (1 eV < E < 4 keV)

The epithermal cross sections between 1 eV and 4 keV are described in terms of single-level, Breit-Wigner, s- and p-wave resonance parameters (File 2) and smooth background cross sections (File 3). Table 1 lists the measurements used in the evaluation of the s-wave resonances.<sup>9-14</sup>

One objective of the present evaluation was to minimize systematic differences between the various experiments as much as possible. Perhaps this could best be done by reanalyzing each of the measurements on a resonance-by-resonance basis using the same analysis technique.<sup>7</sup> However, because this approach would have been too time consuming for the present evaluation, a type of regression analysis was used instead.

In the regression analysis approach, the neutron widths are normalized to a common basis.<sup>8</sup> The measurements of Rahn et al.<sup>9</sup> and those of Carraro and Kolar<sup>12</sup> each span the full energy range 1 eV to 4 keV; therefore, either could be used as the basis for

- 124 -

normalization. The Columbia University data<sup>9</sup> were selected, however, because of the rather large strength functions associated with the Carraro and Kolar data, particularly at higher energies. The resonance energies and  $\Gamma_n$  values of Rahn et al. provide an appropriate standard since they were obtained from a self-consistent analysis of high resolution transmission, self-indication, and Moxon-Rae capture measurements for seven different <sup>238</sup>U sample thicknesses.

The regression analysis, of course, does not account for systematic errors within the Columbia measurement itself. A final normalization of the neutron widths was planned to improve the agreement with measured values of  $\rho^{28}$  (the ratio of epithermalto-thermal <sup>238</sup>U neutron captures) for benchmark lattice experiments, but this was not done when the results were found to be too insensitive to be useful.

Below 1 keV, the regression analysis consisted of determining the constant C in the relation

 $Y_{i} = CX_{i}$ , where i = 1, 2, ..., N

In this relation,  $X_i$  denotes the ratio  $\Gamma_n/E_0$  determined by Rahn et al. for the s-wave resonances, and  $Y_i$  denotes the same ratio but as determined from one of the other experiments in Table 1. The index N denotes the number of s-wave resonances below 1 keV. A similar procedure was used to normalize the Carraro and Kolar data to the Rahn et al. data between 1 and 4 keV. The values of C determined from the regression analysis are given in Table 2.

- 125 -

Values of C greater than unity indicate measurements having neutron widths that are on the average greater than those of Rahn et al. The neutron widths of each of the experiments were therefore multiplied by the reciprocal of C to remove the systematic differences.

After the neutron widths were normalized by the regression analysis, the resonance parameters were evaluated on a resonanceby-resonance basis to determine  $E_0$ ,  $\Gamma_n$ , and  $\Gamma_\gamma$ . As part of the evaluation process, the capture resonance integral and the peak capture and total cross sections for each of the various normalized experiments were compared. Tables 3, 4, and 5 give the resonance energies, the normalized neutron widths, and the capture widths for each of the s-wave resonances below 1 keV. The corresponding values for the capture resonance integral and the peak capture and total cross sections for each of these resonances are listed in Tables 6, 7, and 8.<sup>\*</sup> The appropriate formulas are:

Capture integral $I_{\gamma} = \frac{a\pi}{2} g \frac{\Gamma_n \Gamma_{\gamma}}{\Gamma E_0 2}$ Peak capture cross section $\sigma_0^{\gamma} = a g \frac{\Gamma_n \Gamma_{\gamma}}{E_0 \Gamma^2}$ Peak total cross section $\sigma_0^{\text{total}} = a g \frac{\Gamma_n}{E_0 \Gamma}$ 

where the left-hand side of each of the equations is in barns,

<sup>\*</sup> Tables 6, 7, and 8 do not indicate the resonance parameters below 100 eV because these parameters are unchanged from Version III.

energy is in eV, g is the statistical spin factor,

$$\Gamma = \Gamma_n + \Gamma_{\gamma}, \text{ and}$$
$$a = 2.6032 \times 10^6.$$

The resonance parameters that yielded the most consistent values for  $I_{\gamma}$ ,  $\sigma_0^{\gamma}$ , and  $\sigma_0^{\text{total}}$  were selected for the ENDF/B-IV evaluation. Special attention was given to maintaining the coupling between  $\Gamma_n$  and  $\Gamma_{\gamma}$  determined in the individual experiments.

The ORELA capture measurements<sup>10</sup> are not reported in terms of resonance parameters; therefore, these measurements had to be factored into the evaluation by an indirect method. The measured capture probabilities as a function of energy below 4 keV have been compared to Monte Carlo calculations using ENDF/B-III data (Figure 1). These comparisons of the capture probabilities together with the Version III resonance parameter information in Tables 3 through 8 provided the needed link to at least qualitatively include the inferences of the ORELA measurements.

Table 9 summarizes the evaluation of the s-wave resonances. Version III and Version IV evaluations differ very little. The infinite dilution resonance integrals in Table 9 were calculated using the narrow resonance approximation. The small differences between the Version III and Version IV infinite dilution resonance integrals probably translate to even smaller differences for effective integrals with high self-shielding.

The current File 2 resonance parameters contain an error, which causes the representation of the subthreshold fission

- 127 -

widths ( $\Gamma_{\rm f}$ ) in ENDF/B-IV to be incorrect. Under the assumption that  $\Gamma_{\rm Y}$  is 23 meV, the ENDF/B-IV compilation gives fission widths of 0.29 and 0.051 meV for the 720- and 1210-eV resonances, respectively. But in Reference 5, these fission widths correspond to Class II levels with radiation widths of 4.9 meV. When the resonances are assigned to the first well of the double-humped fission barrier,  $\Gamma_{\rm Y}$  is 23 meV, and  $\Gamma_{\rm f}$  is 1.2 and 0.12 meV for the 720- and 1210-eV resonances, respectively.

The measurements used in the evaluation of the p-wave resonances are listed in Table 10.9,10,15,16,17

Table 11 gives a partial list of the experimentally determined neutron widths (multiplied by the statistical spin factor, g)<sup>\*</sup> and the resonance energies. The ENDF/B-III p-wave parameters were derived almost entirely from the data of de Saussure et al.<sup>10</sup> and hence provide a measure of the neutron widths for that experiment.

Although the experiments themselves do not isolate the sand p-wave resonances, it is generally easy to distinguish them because the p-wave levels are typically much weaker. As indicated in Table 11, some experimenters have differed in the assignment of some of the resonances that can be considered as strong p-wave or weak s-wave resonances. With the exception of the resonance at

<sup>\*</sup> The experiments cannot determine g, which can equal 1 or 2 depending on the spin of the compound nucleus.

263.9 eV, the ENDF/B evaluation has used the statistical analysis of Rahn et al.<sup>9</sup> to distinguish weak levels as p or s. The 263.9-eV resonance must be p-wave to conserve parity since measured spectra for the resonance exhibit El radiative transitions to the  $5/2^+$  ground state of  $^{239}$ U.<sup>18</sup>

In the evaluation below 1200 eV, a supposed p-wave resonance of an experiment was considered spurious and hence ignored if it was not substantiated by another of the experiments considered. For each established p-wave resonance, the neutron width was determined by weighting the measured values according to their reported experimental precision. The Version IV p-way: parameters between 1.2 and 4 keV are almost the same as those in Version III, but with minor modifications to improve the agreement with the ORELA capture cross section measurements.

The p-wave resonance parameter evaluation is summarized in Table 12. Again, only small differences are observed between the Version III and Version IV evaluations. The ENDF/B-IV strength function of  $1.89 \times 10^{-4}$  is based on the p-wave resonances below 500 eV. This value, determined using a channel radius of 8.4 fermi, is consistent with the p-wave strength function obtained from the cross sections in the 10-40 keV range.

The background cross sections between 1 eV and 4 keV that went into File 3 will now be described. A scattering cross section of approximately 2.5 barns was added between 1 eV and the first resonance to provide continuity across the breakpoint

- 129 -

at 1 eV. This addition is required because File 2 includes only the positive energy resonances with their associated interference scattering terms. A similar spectrum of bound level resonances exists and is the origin of this additional 2.5 barns contribution. Capture cross sections between 1 and 100 eV were also added to account for the bound level contribution.

In addition, background cross sections between 0.68 and 4.0 keV were added to account for missed p-wave resonances in the resolved region. These background cross sections are compared with those in Version III in Table 13.

#### CONCLUSION

ENDF/B-III and ENDF/B-IV calculations of  $k_{eff}$  and  $\rho^{28}$  for ten CSEWG thermal benchmark experiments are given in Tables 14 and 15.

The five unreflected spheres of uranyl nitrate solution contain 93 wt %  $^{235}$ U and serve as a test of the H<sub>2</sub>O and  $^{235}$ U cross sections. The relatively good prediction of criticality for the spheres, particularly for Version IV, indicates no severe problems with H<sub>2</sub>O and  $^{235}$ U cross sections in thermal systems.

The two H<sub>2</sub>O-moderated lattices of slightly enriched uranium and three D<sub>2</sub>O-moderated lattices of natural uranium rods test the  $^{23\theta}U$  thermal and resonance region capture cross sections, in addition to the  $^{235}U$  and moderator cross sections. Although the improvement over Version III is significant, the Version IV calculations still underpredict criticality. Again, this can be

- 130 -

の社会学家が大学会がないないないないです。

traced to the overprediction of  $\rho^{2\,\theta}$ . Reasonably good predictions of criticality would be achieved if the required reduction in epithermal-to-thermal <sup>238</sup>U captures could be accomplished.

Good prediction of criticality could therefore be achieved for the uranyl nitrate solutions and the lattice experiments if epithermal neutron capture in <sup>238</sup>U were reduced to yield agreement with  $\rho^{28}$  measurements. In light of the present evaluation, however, the required reductions of the epithermal <sup>238</sup>U cepcure cross sections appear to be below the bounds esta<sup>1</sup> lished by the precision of present differential measurements. Thus, the difficulties encountered in thermal data testing may be arising, at least in part, from sources other than cross sections.

FIGURE 1 Comparison of ENDF/B-III and ORELA Capture Measurements

Comments on the U-238 Discrepancy

R. E. Chrien Brookhaven National Laboratory

The performance of thermal reactors using light water moderation and slightly enriched uranium fuel is not well predicted from microscopic nuclear parameters. The problem lies in neutron capture by U-238. The capture is overpredicted using commonly accepted resonance parameters from the ENDF-B IV file, and as a consequence the predicted critical eigenvalue for thermal critical assemblies is significantly less than one.

Because the urarium is present in lumped fuel elements, the quantity of most importance is the heavily shielded resonance capture integral. Phrased in another way, it is the cross section between resonances which assumes crucial importance in this instance. Since the dilute resonance integral is fixed to the measured thermal capture cross section, through the device of assuming a sufficient bound level cross section, we can be reasonably sure that the cross section in the thermal region, and below the first resonance at 6.67 eV, is adequately represented by the parameters.

Above the 6.67 eV resonance however, there is a mechanism which could lead to an over estimate of the true capture cross section, if the parameters have been selected to produce the correct thermal cross section. This mechanism is the existence of an asymmetry in the 6.67 eV capture resonance. Now, in fact, the symmetry imputed to a capture resonance is essentially approximate in character, resulting from the large number of exit channels available for radiative capture. The radiative width amplitudes have random signs, and the sum of a large number of these causes approximate cancellation of level-level interference effects.

In U-238, however, it is well known<sup>1,2</sup> that the capture from thermal to the first resonance exhibits an anomalously high probability for populating the 720 keV  $1/2^{-1}$  state of U-239. At thermal this 4059 keV line represents ~ 11% of total capture, far larger than any of the others. Accordingly, the presence of this anomalous transition may introduce a significant asymmetry in the shape of the first resonance. The interference associated with this transition is <u>constructive</u> below the 6.67 eV resonance, and destructive

- 147 -

above.<sup>1</sup> Since a fit to total capture is forced at thermal, the result of this asymmetry is a reduction of the cross section above the resonance. Use of a normal Breit-Wigner curve will consequently over-predict the cross section above 6.67 eV.

The effect has been estimated as follows: We assume the asymmetry is due only to the 4059 keV Y-ray populating the 720 keV  $1/2^{-1}$  state; all others are assumed to sum to zero. We use the resonance parameters of BNL 325 and the previously measured resonance partial widths.<sup>1</sup> We assume the Y-ray transition strengths as measured by Sheline et al.<sup>2</sup>

The resulting curves and tables are included in this report. As expected, there is very little effect below 6.67 eV. Above this energy there is a significant reduction in capture cross section due to destructive interference. The effect is largest near the interference minimum at 10.2 eV (the p-wave resonance near this energy has been ignored). The effect while small in cross section, is a large fractional effect--about 7%--in the region near 19 eV.

Two experiments can be done with the equipment at HFBR which are crucial in resolving the U-238 capture discrepancy. The first is to do a precise measurement of the capture cross section in the wings of the U-238 resonance; i.e. from 0.0253 eV to about 3 or 4 eV, and from 8 eV up to about 15 eV. I propose to do this by the activation technique using the monochromatic beam from the crystal monochromator at H-1A. From these experiments the degree of asymmetry of the 6.67 eV resonance can be determined, and a precise value of the thermal capture cross section of U-238 obtained. While the presently-accepted number, 2.7 is reputedly known to 1%, the value should be checked as it is crucial to the calculation of capture in this region. The second experiment is a precise measurement of the total radiation width of the 6.67 eV resonance, and possibly the 20.9 eV resonance. These resonances contribute a major share of the resonance capture integral of U-238, and their values should be determined to 5%. It seems almost certain that if the discrepancy in U-238 capture can be attributed to the microscopic cross sections, then it is this energy region where the parameters are in error. The measurement is to be done by measuring total cross section, capture, and self-indication areas of these resonances, using the HFBR fast chopper.

NOTE ON THE CAPTURE WIDTH OF THE 6.67 eV LEVEL IN 238U\*

G. de Saussure and R. B. Perez Oak Ridge National Laboratory Oak Ridge, Tennessee 37830

At a recent "Seminar on <sup>238</sup>U Capture" the suggestion<sup>1</sup> was made that the capture width of the 6.67-eV level in <sup>238</sup>U might be appreciably smaller than the value 25.6 meV evaluated in Versions III and IV of ENDF/B.

The suggestion was based, in part, on a comparison between a Monte Carlo calculation and a measurement of the capture probability in a thick sample of  $^{238}$ U.<sup>2</sup> For the level at 6.67 eV the calculation indicated a broader peak than the measurement (Fig. 1).

In this note we present a few comments on this argument.

1. The measurement and calculation referred to (illustrated in Fig. 1) were not done for the purpose of determining the capture width of the 6.67-eV levels, but were done to normalize a time-of-flight measurement by the saturated resonance technique. For such normalization, the only quantity of importance is the value of the capture probability on the "flat top" of the peak, and this quantity is insensitive to the value of the capture width.

The relative energy scales of the calculation and of the measurement shown in Fig. 1 were not well aligned, and the calculation was made assuming a disk of infinite radius, whereas the measurement was done with a disk of 7.65 cm diameter. Hence, it seems unwise to conclude from Fig. 1 that the capture width of the 6.67-eV level is smaller than that used in the calculation (25.6 meV).

Research sponsored by the Energy Research and Development Administration under contract with the Union Carbide Corporation.

- 151 ~

2. An attempt was made to see if our previous measurements of the capture probability in the saturated 6.67-eV level could yield information of the capture width of that level, in spite of the fact that the intent of the measurements was not to determine that width.

The Monte Carlo program was refined to include the effect of the finite size of the capture sample, and calculations were done with capture widths of 21, 23, and 25.6 meV for sample thicknesses of .002849 a/b and .000789 a/b.

The calculations were compared with a set of nine measurements recently done with those two sample sizes.<sup>3</sup> The experimental background could not be measured directly with sufficient precision, so the calculations were fitted to the measurement and a "free" background. The results of this comparison are illustrated in Table I. In Fig. 2 we compare one run with calculations done with capture widths of 21 and 25.6 meV.

As shown in Table I the data from the nine saturation measurements examined seem to favor a value of 23 meV for the capture width of the 6.67-eV level in <sup>238</sup>U. But this conclusion is barely statistically significant. Furthermore there is at least one possible experimental effect which could reduce the apparent capture in the wings of the resonances.

Neutrons with energies near 6.67 eV have a very short mean free path in the sample and hence are captured on the surface of the sample. However, neutrons in the wings of the resonance are captured nearly uniformly through the sample. Hence, the capture gamma rays produced by the

- 152 -

のないないないである。このではないないないです。

latter neutrons are perhaps more attenuated by the sample. We don't know how to compute reliably the magnitude of this effect, in th complicated geometry of the experiment and a realistic estimate should come from measurements with "split samples."

in the part of the

ş.

ŝ

11.00

In conclusion, our previous measurements of the capture rate in thick samples of <sup>2:8</sup>U were not designed to determine the capture width of the 6.67-eV level and do not provide reliable information on this width. An analysis of recent measurements seems to favor a value of 23 meV for this capture width, but additional experiments especially designed for the purpose would be most desirable.

.

The experimental data were fitted to a function  $A \cdot S(E,\Gamma_{\gamma}) + B$  where  $S(E,\Gamma_{\gamma})$  is the capture probability computed for a given value of  $\Gamma_{\gamma}$  by a monte Carlo program. The number in columns 3 to 5 are proportional to the weighted sums of the residual for the fit. The numbers in columns 6 to 8 are the values of B obtained by the fits. In column 9 is given one estimate of B obtained inde-pendently of the fit (with a "background scaler").

COMMENTS ON 238 U NEUTRON WIDTH EVALUATIONS

#### H. DERRIEN

#### CEN - SACLAY, FRANCE

The present situation of  $^{238}\text{U}$  résonance parameters as it is seen by Europeen experimenters and users is reported in the proceedings of the Specialist meeting on "Resonance Parameters of fertile nuclei and  $^{239}\text{Pu}^{\text{u}}$  held at Saclay on 20-22 May 1974 [1] . At this meeting a new evaluation of the  $^{238}\text{U}$  resonance parameters has been proposed by M. MOXON [2] . Some preliminary results concerning new measurements in progress at Geel have been given by POORTMANS et al [3]; other details about these new measurements were given by F. CORVI et al at the last Washington Conference [4].

The parameters recommended by M. MOXON are an average of all the weighted values presently available in the litterature (from all the measurements performed since 1955). The high  $\chi^2$  value he obtained from the comparaison of the various sets of neutron widths (2422.1 for 679 degrees of freedom) indicates that there are some systematic differences in these sets of data or that some of the uncertainties have been underestimated. As a matter of fact, MOXON has shown, by checking "the fractionnal difference FN in  $\Gamma_n$  between the data from a given reference and the weighted mean value from the other available data", that correlation exists for some data sets between FN and the neutron energy (for instance negative correlation in the GARG data [5] and positive correlation in the CARRARO data [6]). The origin of these systematic differences, as MCXON pointed out, could be found in : i) the type of presument; ii) the method of analysis; iii) the Doppler and resolution effects. There is however a lack of information concerning the possible source of errors (background determination, self-screening correction, multiple scattering, effective temperature of the sample, influence of the finite cut off to the resonance areas...) In view of this situation. MOXON has concluded that it is not possible to make a choice among the various sets of data. According to MOXON, the best set of resonance parameters which can be recommended at the present time is obtained by averaging all the available values, with (arge error bars on each averaged value. This rather pessimistic conclusion only shows that the problem of  $^{2360}$  resonance parameters is still far from being solved. Yet,the most recent measurements reviewed in the MOXON evaluation have been made with very high resolution with the purpose of obtaining very accurate resonance parameters is the Columbia measurements, as reported by RAHR et al. 171 and the Geel measurements, as reported by CARRARO et al. 181., 161. These works took advantage of all the improvements of the last few years in the time of flight techniques and in the method of analysis; the results should therefore be better than those from the earlier experiments. Still, at least beyond 1.5 KeV neutron energy, severe discrepancies exist between the  $^{-}_{\rm in}$  values ibtained by RAHN and CARRARO. And now, the problem is : will the new measurements in progress at Geel give an explanation to these discrepancies or will they provide one more set of parameters different from the others ?

Indeed, performing new measurement can be useful if one can trust the results and if one knows why the new results should be better than the older ones; this was probably MOXON 's feeling when he did his evaluation. But there is another way of checking the existing data, before decidie, about the necessity of a new measurement : it is to use the same analysis technique for several sets of experimental data. Of course, it would be a very lengthy procedure if all data had to be re checked in this way. But it seems to us that checking simultaneously the Columbia and the Geel transmission measurements would provide and accurate set of in valung, In the last few years, we have shown that the best and quickest way to do this kind of evaluation is to use least square shape analysis method 191, 1101, which is able to bring out the systematic errors in the transmission experiments (mainly in the background evaluation and in the normalization). Furthermore, the difficulties arising from the contribution of neighbouring resonances, the Doppler and resolution effects, the Knowledge of the effective potential scattering can be easily canceled in the shape analysis. For instance, the code used at Saclay allows simultaneous analysis of 5 transmission series and 100 resonances. Such work, on Columbia and Geel transmissions would take three or four months for an evaluator and would be much less expensive than a new measurement.

We have tried this method in two energy intervals of the Columbia and Geel data. But before giving comments on the results, one remark is of interest: the situation when comparing the Columbia and Geel ' values is not too bad up to 1.5 KeV neutron energy. Table I shows how the sum of In obtained from the values published by CARRARO et al. at Helsinki and the values published by RAHN at Knoxville compare each others. Only beyond 1.5. KeV the situation becomes critical and needs to be examined very carefully. Up to 1.5 KeV, average values of Columbia and Geel results would provide fairly accurate estimation of In values.

Table II and table III show the results in the two energy ranges we analysed (results shown in table II have also been published in the proceedings of the May 1974 Saclay meeting). The time for this work was about 4 days for one physicist and needed about 15 minutes of computers time on IBM-360-91; this gives an idea of the cost of an eventual  $\frac{238}{10}$  U in width evaluation by this method throughout the energy

range where the resonances are resolved (0 eV to 4500 eV). In the 1.4 to 1.8 KeV energy interval (table III), it appears that the values we obtain from the shape analysis of Geel and Columbia data, and the values published by RAHN (area analysis) are in agreement within less than 4% on the average, while the CARRARO values are 15 % to 20 % higher. The reason for the discrepancy between CARRARO values and the others does not appear clearly, because the background correction in the shape analysis remains negligible or weak in each case. But it seems that the RAHN values are better than those of CARRARO in this energy range.

Between 2.5 XeV and 2.8 XeV (table 111) the situation is reversed. The values published by CARRARO et al. at Helsinki agree fairly well with the values obtained from our shape analysis of the Geel and Columbia data, while the RAHN values are more than 10% lower on the average. Here also, the origin of the discrepancy between the RAHN values and the others is not apparent. The shape analysis of the two sets of transmission data give consistent results while the values given by the experimenters are in discord.

From these analysis no information can be obtained concerning the walues. At such high energies the shape analysis cannot provide accurate value of  $\mathbb{C}_{Y}$ . The Doppler and the resolution widths are too large compared to the total width  $\mathbb{C}$  of the resolution widths are too large compared to the total width  $\mathbb{C}$  of the resonances. The difference betweenfand in has the same order of magnitude than the error on the determination of  $\mathbb{C}$ ; furthermore, the comparison between the  $\mathbb{C}$  and  $\mathbb{C}_{pl}$  obtained is used to check the resolution width which is not always very well known. But, it must be pointed out that the discrepancies between Geel and Columbia appear particularly in the large  $\mathbb{C}_{p}$  values. For such large neutron widths, the determination of  $\mathbb{C}_{p}$  from the capture area is not affected by the errors on  $\mathbb{C}_{p}$ . An evaluation of the neutron widths by comparing the Geel and Columbia Transmissions would thus have very little consequence on the nublished Columbia  $\mathbb{C}_{p}$  values.

#### CONCLUSION

The above comments indicate that it is possible to improve the evaluation of  $^{2350}$  resonance parameters by checking very carefully the existing sets of experimental data. Here, we have only considered two sets of experimental transmissions which are probably the most accurate up to now. It is obvious that the differences between the  $T_{\rm e}$  values obtained by RAHN and CARRARO are mainly due to the analysis teschnique : area analysis using the intersection of curves in the  $(T_{\rm e}, T_{\rm e})$  plan or ATIA-HARVEY less square area analysis. Other investigations have to be done concerning the capture data for which the shape analysis method cannot be used if they arm not corrected for experimental effects like selfscreening and multiple scattering. It would be of great interest to know the exact value of the capture area for each resonance directly from a corrected capture cross-section. Apparently that has been done by the Los Alamos physicists for  $^{236}$ U, the  $T_{\rm e}$  obtained by using the Los Alamos capture area and RAHN  $T_{\rm e}$  values are much lower than the other values. An important step in the evaluation of the  $^{230}$ U resonance parameters will be made, if this anomaly is explained.

COMMENTS ON TABLE III

The Geel shape analysis has been done on the 0.011at/b sample; no background correction is needed; but the normalization coefficient is egal to 0.975. The Columbia shape analysis has been done on the 0.084 at/b and 0.035 at/b samples; the background corrections are respectively equal to 0.007 and 0.013, at 2600 eV neutron energy.

The theoretical formulation of the transmission used in the shape analysis is the following :

$$\Gamma_r = a + c \left( e^{-n\sigma_A} \right) \mathbf{x} R$$

 $\sigma_A$  is the usual Breit-Wigner one level formulation of the total cross section, broadened by the Doppler effects, plus one term taking into account the level-level interference in the neutron channel; R is the resolution function, a the background parameter and c the normalization coefficient.

## Review of Benchmark Experiments R. Sher and S. Fiarman Stanford Univ.

This paper discusses some possible systematic errors in reaction rate measurements in lattices, which might be correctable, even at this late date. These include streaming through catcher foils or gaps, fast source perturbations due to the use of depleted uranium detectors and cadmium, and cadmium cut-off effects.

1) <u>Streaming</u>: Some of the lattice measurements were done with 0.001" aluminum catcher foils on either side of the detector foil. Resonance neutron streaming through the "gap" thus formed would cause increased resonance activation of the detector foil. This would make the measured value of  $\rho_{28}$ too high. There is not much data on streaming effects, but two sets of relevant measurements do exist: one, some work ione by Baumann and Pellarin<sup>(1)</sup> at SRL in 1964, the second, some measurements done at MIT<sup>(2)</sup>. These indicate that for small gaps, the resonance activation is increased a few percent per mil. Corrections for this have not been applied to the MIT benchmark natural uranium  $D_2^0$  lattices; however the MIT experiments were done in a different set of lattices (0.250" rods,  $UO_2$ ).

Baumann and Pellarin's measurements were done on natural uranium metal rods of 0.350" and 1.00" diameters, and show effects of the same order of magnitude. They calculate the increase in resonance absorption by a geometric calculation in which the energy integral over an artificial resonance is used, the resonance being designed to give the proper amount of shielded resonance absorption. Essentially the calculation computes the fraction of the difference

- 163 -

1414 A.M. 2010

between the rod resonance integral and the isolated foil resonance integral attributable to the gap.

We have done a similar energy integral calculation but using a simple Monte Carlo approach to treat the geometry and get good agreement with the MIT data and with the SRL data for small gaps. The Monte Carlo calculation does not agree well with Baumann's cruation, but we believe we have found an error in Baumann's equation which removes the discrepancy. Since we are calculating the <u>ratio</u> of activation with streaming paths to without streaming puths, we feel that despite the simple method of treating the resonance region and the neutron flux, either calculational method can be applied to any given lattice. For the 1" natural uranium MIT lattices, the correction is of the order of 5% per míl.

2) <u>Source perturbations</u>: These fall into 2 classes: for the  $\delta_{28}$  measurements, the depleted detector foil and associated catchers form a region in which there are no thermal fissions and therefore the local fast neutron flux is depressed. This lowers the value of  $\delta_{28}$ . For  $\circ_{28}$  and  $\delta_{25}$  the cadmium cover produces a similar effect by suppressing local thermal fissions.

Price at MIT has calculated the correction to  $\delta_{28}$  in terms of a mean chord length for a fast neutron in the fuel rod. This correction applies only to the fraction of fast fissions that are caused by neutrons originating in the same fuel rod; the interaction fact is unaffected by the perturbation. He finds a correction fact.

$$M_{28} = \frac{\frac{\delta_{28} \text{ (true)}}{\delta_{28} \text{ (measured)}}}{\frac{1}{28} = \frac{1+\frac{\overline{\omega}}{\overline{L} + \lambda_R} \frac{V_f}{V_cell}}$$

- 164 -

where  $\vec{\omega}$  is the mean chord length for fast neutrons in the detector foil and  $\vec{t}$  is the mean chord length for fast neutrons in the fuel rod.

For the benchmark lattices,  $M_{28}$  was not determined. For an isolated  $k^{\prime\prime}$  nat, U rod, it was 1.039; this is an upper limit for the MIT benchmark lattices. This correction will <u>worsen</u> the existing discrepancies in  $\delta_{28}$  for these lattices.

The corrections for  $\frac{28}{28}$  and  $\frac{3}{25}$  arise from the suppression of the local fast neutron source caused by the presence of the cadmium. The corrections calculated by Price with a first-flight collision model are of the form:

$$c_{28} = c_{meas}^{28} + A(c_{28})_{SR} = c_{28}^{meas} + C_{23}$$
  
 $\delta_{25} = \delta_{25}^{meas} + B(\delta_{28})_{SR} = c_{25}^{meas} + C_{25}$ 

where A and B are constants which depend principally on ratios of cross sections averaged over fission spectra and thermal spectrum, enrichment.

Price evaluated A and N, but used a (grossly) incorrect  $(\delta_{28}) \otimes R$  , and then badly underestimated the effect.

For the MIT benchmark lattices, we have re-evaluated  $C_{28}$  and  $C_{25}$  and obtain  $C_{28} = 0.026$ ,  $C_{25} = 0.0019$ . These are in the right direction to improve the agreement between measured and calculated values.

3) <u>Cd cut-off</u>: In general there has been no systematic and complete treatment of the cadmium cut-off in those benchmark measurements which determine  $\rho_{28}$  and  $\delta_{25}$  by the cadmium ratio method. Hardy has pointed out that to explain the typical discrepancies between measured and calculated  $\rho_{28}$  values the Cd cut-off would have to be well <u>above</u> 0.625 eV. Although this may be improbable, a rigorous calculation of the Cd cut-off energy should be attempted for the benchmark lattices.

### REACTIVITY AND REACTION RATE MEASUREMENTS IN U-D<sub>2</sub>O LATTICES WITH COAXIAL FUEL

D. J. Pellarin

B. M. Morris

Savannan River Laboratory E. I. du Pont de Nemours & Co. Aiken, South Carolina 29801

### INTRODUCTION

Material bucklings and reaction rate parameters were measured for heavy water  $(D_2O)$  moderated, uniform lattices in the exponential facility (SE-SP)<sup>1,2</sup> at the Savannah River Laboratory (SRL). Two different slightly enriched, coaxial, uranium fuel assemblies were examined over a wide range of triangular lattice pitches in this study. Results of experiments were compared with RAHAB computations using ENDF/B-JV cross sections.

Previous analyses of benchmark U-D<sub>2</sub>O data involving both buckling and parameter measurements have been restricted to simple rod 1. tices.<sup>3</sup> The purpose of this work was to expand the experimental data base to include uniform lattices of coaxial fuel assemblies. Assembly geometry and fuel composition are summarized in Table 1. Integral parameters are reported for inner and outer fuel separately, providing data for a more detailed and rigorous comparison with computation than previously available.

The information contained in this article was developed during the course of work under Contract No. AT(07-2)-1 with the U. S. Energy Research and Development Administration.

By acceptance of this paper, the publisher and/or recipient acknowledges the U. S. Government's right to retain a nonexclusive, royalty-free license in and to any copyright covering this paper, along with the right to reproduce and to authorize others to reproduce all or part of the copyrighted paper.

### SCOPE OF EXPERIMENTS

The lattice experiments using Type I fuel were completed at 5.5-, 6.0-, 7.0-, and 8.0-in. triangular pitches with  $D_2O$  purities ranging from 99.50 to 99.37 mol %.

The lattice experiments using Type II fuel were completed at 6.35-, 7.0-, 8.08-, 9.25-, and 14.0-in. triangular pitches with  $D_2O$  purities ranging from 99.54 to 99.13 mol %. The 6.35-in, pitch case was reassembled at the end of the experimental program, and measurements were repeated to check the experimental reproducibility. Results were duplicated within about 1-1/2%.

### PARAMETERS MEASURED

Reactivity and reaction rate parameters that were calculated from experimental data are summarized below:

<sup>238</sup> U (n, $\gamma$ ) Capture Ratio,	$\rho_{28} = \frac{\text{Epi Cd}^{238} \text{U Captures}}{\text{Sub Cd}^{238} \text{U Captures}}$
<sup>235</sup> U Fission Capture,	$\delta_{25} \approx \frac{\text{Epi Cd}^{235} \text{U Fissions}}{\text{Sub Cd}^{235} \text{U Fissions}}$
<sup>230</sup> U Fast Fissions,	$\delta_{2.6} = \frac{2^{3.8} U \text{ Fissions}}{2^{3.5} U \text{ Fissions}}$
Modified Conversion Ratio,	$C^* = \frac{2^{38} \text{U Captures}}{2^{35} \text{U Fissions}}$
Thermal Neutron Spectral Index (spectral hardening),	$R = \frac{\begin{bmatrix} 1^{76}Lu/^{63}Cu \end{bmatrix}_{Fuel}}{\begin{bmatrix} 1^{76}Lu/^{63}Cu \end{bmatrix}_{Fuel}}$ Thermal Ref.
Material Buckling,	$B_m^2 = B_R^2 + B_7^2$

Intracell thermal neutron activation profiles also were measured. The measurements were made in the exponential facility (SE).

- 168 -

### DESCRIPTION OF SE-SP FACILITY

The exponential tank, 5 ft in diameter and 7 ft high, is mounted directly over the SP, a small, fully enriched, graphitemoderated reactor that supplies neutrons to the SE through a graphite pedestal. Ac urate top and bottom positioning pins and spacers were used to establish the various pitches in the exponential. The SE-SP facility is shown in Figure 1.

Reference foils in the SP thermal column were irradiated by a thermal neutron flux simultaneously with the lattice irradiations in the exponential tank. A 1/v cadmium ratio of about 3 x  $10^{-4}$ existed at the foil exposure position, so corrections for epicadmium activation were not required for the reference foil activities.

Equilibrium flux spectra, characteristic of the measured lattices, existed in the central region of the SE where the foil activation experiments were made. This was affirmed by radial and axial cadmium ratio mapping measurements using gold pin detectors.

### REACTION RATE MEASUREMENTS

Description of the Fuel Assembly Containing the Foils

The Type I and Type II fuel assemblies consisted of nested inner and outer fuel pairs stacked on an aluminum inner housing to produce uniform, continuous axial fuel columns.

The foil bearing irradiation assembly was placed at the center of the lattice and rotated slowly during irradiation to average any radial flux asymmetry. An inner and outer fuel pair

į

ž

- 169 -

with accurately machined, solid angle slots to accommodate thin, bare, shaped foils and 1/2-inch-thick filler pieces were near the center of the fuel column. The shaped foils were fabricated to fit accurately in the slots, so the specific activation in the foil represented the average reaction rate in the fuel. Epicadmium activations were obtained from foils placed inside a small (0.375in.-dia. x 0.01-in.-thick) cadmium pill box contained in a recess in the lower filler piece about 3 inches from the nearest bare foil.

Bare- and cadmium-covered lutetium-copper-lutetium foil sandwiches and copper foils were suspended in the moderator on thin polyester tape supported on an aluminum wire frame attached to the outer fuel. These data were used to obtain intracell flux and spectral index (R) profiles.

#### Experimental Procedures for p28 Measurements

Measurement of the <sup>238</sup>U (n,  $\gamma$ ) capture ratio ( $\rho_{28}$ ) was made by the indirect or subtraction technique that permitted the epicadmium component of the <sup>238</sup>U captures in the fuel to be determined without cadmium-covered <sup>238</sup>U foils. This method has the advantage of reducing the effect of spectrum distortion produced by cadmium.

Thin (0.003 to 0.004 in.), bare depleted and natural uranium foils were used to determine the total  $^{2\,38}$ U capture rate in the fuel. Identical bare foils were simultaneously irradiated at the thermal reference position (along with copper foils) to normalize the subcadmium  $^{2\,38}$ U capture rate in the fuel.

- 170 -

The neptunium decay was counted 2 to 3 days after irradiation with NaI scintillation counters biased to accept gamma energies in the interval from 90 to 116 keV. A simultaneous count representative of fission product decay activity, obtained at an integral bias of 500 keV, was used to correct for the fission product contribution to the counting rate in the window. The ratio of the fission product counting rate in the 90 to 116 keV window to the fission product counting rate at the 500 keV bias was determined for the actual counting conditions and irradiation times of each experiment. This ratio was obtained for  $^{2\,3\,5}\text{U}$  fission products from the natural and depleted foils in the thermal reference position that were counted with the natural and depleted foils from the lattice. Typically, the fission product correction for the 0.019 wt % depleted foils was about 2%, and was 10% for natural uranium foils. Systematic differences were not noted in the  $\rho_{28}$  values between the two different foil types.

An auxiliary experiment was performed to obtain a factor to correct the average epicadmium specific activity of the two 0.010-in.-thick copper foils in the cadmium pill box in the fuel to the equivalent epicadmium specific activity for a single 0.010 in. copper foil under 0.030 in. of cadmium and dimensionally similar to the shaped bare copper foils contained in the fuel. This correction, about 9%, simultaneously established the effective cadmium cutoff energy for the  $\rho_{20}$  measurement at 0.625 eV, which corresponded to 0.030 in. of cadmium in slab geometry and isotropic flux with a 1/E energy dependence.

- 171 -

Small corrections of 1% for the inner fuel and 2% for the outer fuel accounted for the increase in  $^{230}$ U resonance capture caused by the 0.001-in. gap at the interface between the foils and the fuel where aluminum was placed to prevent fission product contamination of the foils. These corrections were derived from an experiment in which known gaps of from 0.001 to 0.021 in. were introduced. The normalized (normalized to 0.001-in. gap)  $^{239}$ Np epicadmium component of each foil was plotted against foil gap thickness and extrapolated to zero gap to obtain the correction.

Small calculated corrections of about 2% were applied to the measured <sup>239</sup>Np subcadmium activities to account for the difference between the actual average thermal flux at the foil site in the fuel, and what the true thermal flux in the fuel would have been without the foil. Calculated thermal flux depression factors were used to derive these corrections.

Calculated thermal flux depression factors were applied to the copper foils and to the depleted and natural uranium foils in the thermal reference position and in the lattice. These factors were applied consistently throughout the data analyses; therefore, the reported values of  $\rho_{28}$  are for infinitely thin <sup>238</sup>U foil detectors.

Other corrections to the experimental data accounted for:

 Differences (~4%) in gamma attenuation in the 90-116 keV window count caused by small differences in foil thicknesses between the natural and depleted uranium foils.

- 172 -

- Small differences in foil-to-counter geometry. Because small foil-to-counter acceptance angles were used, this correction generally was about 0.3%.
- Differences in the axial elevation of the foils in the experiment. This correction was obtained from a smooth fit of the axial flux based on bare gold pin activations in the moderator.
- Differences in moderator purity. Calculated corrections of 1 to 2% were applied to convert the measurements to 99.75 mol % D<sub>2</sub>O.

#### δ28 Measurement

 $\delta_{28}$  was measured using paired natural and depleted uranium foils in the fuel; 1/2-in.-diameter foils of similar composition and thickness were simultaneously irradiated in a  $\delta_{28}$  reference geometry. The reference was taken as a 1/2-in. recess in a 1-in. natural uranium rod buried in a large graphite moderator block. The assembly was fed by thermal neutrons from the SP. Both sets of foils (i.e., those in the lattice and those in the reference) were counted for fission product activity under the same time and counting conditions. The value of  $\delta_{28}$  in the lattice was derived from the known value of  $\delta_{28}$  in the reference, simple ratios derived from the fission product activities, and known compositions of the foils. The  $\delta_{28}$  values in the lattice are based on a  $\delta_{28}$  reference value of 0.076. This value was obtained by

- 173 -

direct measurement using the standard double fission chamber method. As a check, a value of  $\delta_{28} = 0.053 \pm 0.003$  was measured for an isolated 1-in.-diameter natural uranium rod using this reference technique. This value is in good agreement with a measurement by Bigham,<sup>4</sup> giving  $\delta_{28}$  as 0.050 ±0.001 for the isolated 1-in.-diameter natural uranium rod.

### δ25 Measurement

The <sup>235</sup>U fission capture ratio ( $\delta_{25}$ ) was determined by activating bare and cadmium-covered, diluted <sup>235</sup>U-Al foils in the fuel.

### C\* Measurement

The modified conversion ratio (C\*) involved the measurement of relative <sup>238</sup>U (n, $\gamma$ ) capture rates and the <sup>235</sup>U fission rates in natural and depleted uranium foils. The foils were irradiated simultaneously in the lattice and in the thermal reference position.

## R Measurement

The activation ratio of subcadmium captures in  $1^{76}$ Lu to subcadmium captures in 63Cu within the fuel is a parameter related to the energy distribution of the neutron flux.  $1^{76}$ Lu has a resonance at 0.14 eV and 63Cu is a 1/v absorber. Normalization to the same ratio in the Maxwellian spectrum at the thermal reference position provides a thermal neutron spectral index, R, that is a measure of the thermal neutron spectrum hardening in the fuel.

~ 174 ~

Comparison of Experimental Results with Computation

The experimental results were compared with RAHAB<sup>5</sup> computations. RAHAB uses multigroup integral transport theory and the Nordheim resonance treatment to perform lattice cell computations. For uniform lattices, RAHAB is similar to the HAMMER<sup>6</sup> code. ENDF/ B-IV cross sections were used. The comparisons are summarized in Table 2 for the Type I fuel and in Table 3 for the Type II fuel. The standard deviations represent a one-sigma range based on the statistics of duplicate determinations.

The following observations were noted:

- For Type I fuel, ρ<sub>2θ</sub> (outer fuel) is slightly overpredicted by about 4% on average, while ρ<sub>2θ</sub> (inner fuel) is consistently overpredicted by about 22% on average (Figure 2).
- For Type II fuel, ρ<sub>28</sub> (outer fuel) is overpredicted by about 11%, while ρ<sub>28</sub> (inner fuel) is overpredicted by about 20% (Figure 3).
- Computations overpredict the ratio of epicadmium to subcadmium <sup>235</sup>U fissions ( $\delta_{25}$ ). For both Type 1 and Type II fuel,  $\delta_{25}$  (inner fuel) is overestimated by about 23% on average; and  $\delta_{25}$  (outer fuel) is overestimated by about 14%.
- C\* is overpredicted for both Type I and Type II fuel; the major disagreement again occurring for the comparison with the inner fuel.
- The RAHAB computations underestimate  $\delta_{2.6}$  for both fuel types by about 11% for the inner fuel, and about 7% for the outer fuel.

RAHAB overcalculates the magnitude of the spectral hardening
 (R) in the fuel.

In general, the discrepancies between experiment and RAHAB computation do not show a pitch dependence. The comparison between experiment and calculation is summarized in Table 4. Also the calculations do less well in predicting inner fuel parameters.

### MATERIAL BUCKLING MEASUREMENTS

#### Experimental Procedures

Material bucklings were measured by flux mapping techniques in the cylindrical exponential facility (SE). Radial and axial curvatures were determined independently and combined to obtain  $B_m^2 = B_R^2 + B_z^2$ .

The ratio of cadmium-covered to bare gold pin activations was determined throughout the exponential, so that regions where flux curvature was energy-dependent could be avoided.

A separate irradiation was made with a cadmium "shutter" between the critical source reactor (SP) and the SE, thereby eliminating from consideration photoneutrons resulting from the gamma field of the SP. The shutter correction also eliminated contributions from neutrons that originated in the SP and were reflected from walls into the SE.

Two methods of profiling were used to determine axial bucklings, depending on whether the material buckling was larger or smaller than the radial buckling.

Exponential profiles  $(B_m^2 < B_R^2)$  were measured with a traveling

- 176 -

ion chamber which sampled flux at 2-cm intervals over a total distance of 60 cm. The axial buckling was determined as the curvature of the best fit to the experimental data points by varying parameters in a hyperbolic cosine function. The perturbation of the flux shape from the traveling monitor itself was found to be negligible.

Cosine axial flux profiles  $(B_m^2 > B_R^2)$  were measured by irradiating gold pins of standardized shape and mass. The gold pins were arranged at 8-cm intervals on stringers of 70-cm length; three such stringers were used for each experiment. In such cases, the data were fitted to a cosine function. The gold pin activations were measured using NaI scintillation counters and include background, decay, and counter deadtime corrections. The traveling monitor could not be used for these more reactive lattices because of the large perturbation induced by the ion chamber.

Both the traveling monitor guide tube and gold pin stringers were near the centerline of the exponential tank. Previous experience has shown, however, that the axial buckling is independent of the radial positions at which the flux profile is measured, provided the edge of the SE is avoided.

Radial flux profiles were measured by irradiation of standardized gold pins. Pins were located at from 12 to 30 interstitial positions within a given horizontal plane, and 3 such arrays of pins at different elevations were included for each lattice pitch. The counting of the pin activations was

- 177 -

similar to that described for the axial measurements. The measured radial flux shapes were fit to a zero-order Bessel function to determine the radial buckling.

Comparison of Experimental Results with Computation

The results of the buckling measurements for both fuel types are given in Tables 5 and 6. Although  $D_2O$  purities varied during the experiments, corrections to a common purity of 99.75 mol % wore calculated and applied to the data. Such calculated  $D_2O$ purity corrections have been verified by experimental measurements.

For both the axial and radial measurements, the standard deviation in flux was approximately 0.5%. This uncertainty in flux induces an uncertainty in buckling which is dependent on the magnitude and nature of the curvature. The standard deviation in axial buckling ranges from 0.10 to  $0.20 \text{ m}^{-2}$ ; and for the radial buckling, the range is from 0.20 to  $0.35 \text{ m}^{-2}$ . These statistical uncertainties in flux and buckling are primarily associated with uncertainties in gold pin mass, gold pin position, and position of fuel assemblies. Repetition of buckling measurements after unloading and reloading of fuel and pins indicates the bucklings can be reproduced to within  $0.10 \text{ m}^{-2}$ .

The major source of systematic error in these experiments is expected to be the application of exponential theory to a lattice. The detailed effects of this approximation on the buckling measurements have not been investigated. However, an SE buckling measurement was compared to a critical measurement.

- 178 -
of the same lattice. The test lattice was very similar to lattice types I and II. The buckling of the test lattice as measured in the critical facility was found to be lower than the SE value by 0.20 m<sup>-2</sup>. No adjustment in the data of Tables 5 and 6 was made on the basis of this information; the error ranges in those tables reflect only the substitutian uncertainties in the measurements.

Bucklings and k<sub>eff</sub> values calculated using the integral transport theory code, RAHAB, and ENDF/B-IV cross sections are also shown in Tables 5 and 6. The differences between measured and calculated quantities increase as the lattice pitch decreases, or as the fuel-to-moderator ratio increases. In all cases, these discrepancies are significantly larger than either the experimental uncertainties or the possible bias between critical and exponential measurements.

### CONCLUSIONS

The underprediction of material buckling and  $k_{eff}$  by RAHAB is consistent with the overprediction of  $\rho_{28}$ , C\*, and  $\delta_{25}$  and the underprediction of  $\delta_{28}$ . It is thought that the major part of these discrepancies may be attributed to the particular resonance capture models employed by RAHAB. The effects of possibly inaccurate differential or evaluated cross section data probably add a smaller contribution.

The detailed reaction rate parameters and the material bucklings presented here constitute a set of data which should complement existing benchmark  $D_2O$  lattice data. Coaxial tube fuel assemblies, such as Type 1 and Type 11, provide a more detailed set of data for comparison of calculation to experiment than is possible for simple rod lattices. Also, the Type 1 and Type 1I fuel at the experimental lattice pitches represent fuel-to-moderator ratios significantly larger than for other measured  $D_2O$  lattices. For example, the 6.35-in.-pitch Type II lattice has a ratio of uranium to deuterium which is a factor of ten larger than that of the highest uranium-to-deuterium (U/D) lattices.<sup>7</sup> The significance of this is that the Type I and Type II lattices enhance the relative number of captures in <sup>238</sup>U and thus present a more rigorous test of calculational methods for resonance capture.

#### INTERFERENCE SCATTEPING EFFFCTS ON INTERMEDIATE RESONANCE ABSORPTION AT OPERATING TEMPERATURES

## R. Goldstein Combustion Engineering

The Intermediate Resonance (IR) approximation provides a relatively simple means of accurately calculating resonance integrals. The IR solution to absorption problems is accomplished through the use of interpolation parameters. Each scattering species of the system is represented by a parameter which bridges the gap between the wide resonance (WR) and narrow resonance (NR) extremes, thereby representing the more practical intermediate case. The values of the interpolating IR parameters depend on the resonance characteristics and the physical properties of the system under consideration and can be determined from analytical solutions based on a successive approximation approach or a variational procedure.

The original IR formulation<sup>1</sup> was carried out at zero temperature without the inclusion of interference scattering. Later the solution was extended separately to the cases including interference scattering<sup>2</sup> or Doppler broadening.<sup>3</sup> More recently, these two effects have been treated concurrently, so that the coupling between interference scattering and Doppler broadening has been included.<sup>4</sup> With this approach it is possible, therefore, to evaluate the effect of temperature on the interference between resonance and potential scattering.

The inclusion of interference scattering effects is more important for the higher energy, more strongly scattering resonances. When these effects are included, the

- 189 -

IR parameters sometimes fall outside the range between 0 and 1, which correspond to the first-order WR and NR approximations, respectively. This situation has been discussed in the literature.<sup>5,6</sup> The actual values of the parameters are not very important, however, and less emphasis should be placed on them. The resonance integrals are the important quantities of interest, and these are still reliable, even when the parameter is less than zero or greater than unity.

Part of the problem which causes this situation and makes extrapolation necessary, is the inadequacy of the firstorder WR approximation. Since the first-order WR approximation completely neglects scattering, interference effects are not reflected in it. Only to second and higher order will the WR approximation reflect scattering effects. The situation is depicted pictorially in Fig. 1. The example is for the case when the first-order WR approximation,  $WR^{(1)}$ , gives a larger resonance integral than the first-order NR approximation, NR<sup>(1)</sup>. This occurs when the resonance and scattering properties are such that  $s\Gamma_n > \sigma_n \Gamma_\gamma$ , where s is the effective scattering of the moderator and  $\sigma_n$  is the potential scattering of the absorber. When interference scattering is neglected, the higher-order approximations converge to a value inside the initial range, so that the IR parameter  $\lambda$  and the IR absorption integral also fall within the initial range.

Figure 2 depicts how the situation becomes altered when interference scattering is included. The inclusion of interference scattering always tends to increase the resonance

- 190 -

Fig. 1: Resonance Integrals Without Interference

$$NR^{(1)}(\varepsilon=0)$$

بالتحمية والمعور والمتحري

Fig. 2: Resonance Integrals With Interference Scattering Included (ε=0 is without interference).

. . .. .

and exercises were the first of the

.....

absorption. As already mentioned, however, the first-order WR approximation is unchanged by interference scattering. Therefore, it can happen sometimes, that the increase in resonance absorption due to the inclusion of interference scattering, causes the second-order NR and WR approximations to yield resonance integrals, both of which are greater than the first-order WR integral. When the resonance and scattering characteristics of a system cause this to occur, the situation depicted in Fig. 2 can result. Also given on the Figure for reference are the resonance integrals without interference ( $\epsilon$ =0).

The successive approximation approach determines that value of the IR parameter  $\lambda$  which equates the first- and second-order resonance integrals. For the situation given in Fig. 2, equality occurs for  $\lambda$  less than zero. With a well-formulated iteration procedure, the IR calculation can still provide a good approximation to the resonance integral; one which is equivalent to a higher-order calculation.

For practical uranium systems, the more common situation is for s to be greater than  $s = \sigma \prod_{o} \prod_{\gamma \in I} r$ . This is the case discussed above and depicted in Fig. 2. However, it is also possible for s to be less than  $s_o$ , in which case the first-order NR integral is greater than the first-order WR integral. When this happens, extrapolated values of the IR parameter, which are greater than unity, can occur.

- 192 -

1.

The extrapolated solution for  $\lambda$  which occurs in Fig. 2 could be avoided by improving the first-order WR approximation. For example, if a small but non-zero amount of scattering were included in this approximation, then the first-order WR approximation with interference scattering included could be made to exceed the second-order results, and the IR parameter would remain between zero and unity. This improved WR approximation is shown on Fig. 2 as a virtual state (V.S.).

Another way of avoiding extrapolation would be to equate second- and third-order approximations as a means of solving for the IR parameter. Since scattering is now included in all approximations, the solution will be within the initial range.

The additional work required for either of these two approaches is probably not warranted, however. Since the resonance integrals from the IR calculations are fairly reliable even when extrapolated values of the IR parameter are used, the latter are still applicable. Sometimes the solutions to the transcendental equations for the IR parameters are multiple-valued. In these cases the appropriate choice can be made on physical grounds. For example,  $\lambda$ less than zero or greater than unity would be chosen for those values of s that are greater or less than  $\sigma_p \Gamma_{\gamma} / \Gamma_n$ , respectively.

Since interference scattering effects decrease with increasing temperature, the inclusion of Doppler broadening

- 193 -

ź

in the IR formulation mitigates the interference effects. The recent IR formalism<sup>4</sup> enables one to investigate the effect of interference scattering at operating temperatures on resonance absorption. Since for the higher energy, more strongly scattering resonances, the use of the IR approximation and the inclusion of interference scattering often tend to act in the same direction of increasing the resonance absorption, it is important in determining temperature effects to evaluate these aspects for each physical system.

The IR results are summarized below for the case of an absorber with potential scattering cross section  $\sigma_p$  and interference scattering parameter  $\epsilon$ , admixed with a non-absorbing moderator of cross section  $\sigma_m$  and located in an NR moderating medium of effective scattering cross section s. The temperature-dependent resonance integral may be written as

$$I_{\kappa\lambda}(\xi) = r\gamma_{\kappa\lambda}J_{\kappa\lambda}(\xi), \qquad (1)$$

and the second

and the second

where

$$\gamma_{\kappa\lambda} = (s + \kappa \sigma_m + \lambda \sigma_p) \Gamma / \sigma_0 (\Gamma_\gamma + \lambda \Gamma_n)$$
 and  $r = 2I^{(0)} / \pi = \sigma_0 \Gamma_\gamma / E_r. (2)$ 

The integral J is a function of both temperature and interference and is defined by

$$J_{\kappa\lambda}(\xi) = \frac{1}{2} \int_{-\infty}^{\infty} f_{\kappa\lambda}(x,\xi) dx \quad ; \quad f_{\kappa\lambda}(x,\xi) = \psi(\xi,x) / [\gamma_{\kappa\lambda} + \psi + \zeta_{\lambda}\chi], (3)$$

$$\zeta_{\lambda} = \epsilon \lambda \Gamma / (\Gamma_{\gamma} + \lambda \Gamma_{n}), \quad \epsilon = \sqrt{\sigma_{p} \Gamma_{n} g_{J} / \sigma_{o} \Gamma}, \quad \xi = \sqrt{A \Gamma^{2} / 4 k T E_{r}}, \quad (4)$$

and  $\psi$  and  $\chi$  are the symmetric and anti-symmetric Doppler-

- 194 -

broadened-line-shape functions.<sup>7</sup>

The IR solution for this case may be written as

$$\lambda = 1 - Z_{\kappa\lambda}$$
 and  $\kappa = 1 - Z_{\kappa\lambda}^{(m)}$ , (5)

$$Z_{\kappa\lambda}^{(i)} = (1/z_{\kappa\lambda}^{(i)}) \tan^{-1} z_{\kappa\lambda}^{(i)} + (i_{\kappa\lambda}^{(i)}/z_{\kappa\lambda}^{(i)}) \log(1+z_{\kappa\lambda}^{(i)^2}) .$$
 (6)

The IR parameters  $\kappa$  and  $\lambda$  correspond to the admixed moderator and the absorber, respectively. The superscript (i) in Eq. (6) refers to either the absorber (for which no superscript is used) or the admixed moderator (for which the superscript (m) is used). The interference quantity  $\mathbf{i}_{\kappa\lambda}^{(i)}$  in Eq. (6) is given by  $\mathbf{i}_{\kappa\lambda}^{(i)} = \mathbf{b}^{(i)}\theta_{\kappa\lambda}/(1-2\mathbf{b}^{(i)}\omega_{\kappa\lambda}), \ \omega_{\kappa\lambda} = \zeta_{\lambda}/\gamma_{\kappa\lambda}, \ \theta_{\kappa\lambda}^2 = \beta_{\kappa\lambda}^2 - \omega_{\kappa\lambda}^2, (7)$ 

where

$$\beta^2 = 1 + 1/\gamma$$
,  $b^{(m)} = \zeta_{\lambda}$ , and  $b = (\epsilon \Gamma/\Gamma_n) [1 - \sigma_p \Gamma_{\lambda} / (s + \kappa \sigma_n) \Gamma_n]^{-1}$ . (8)

Using the scalar product notation to denote integration over the energy variable x =  $2(E-E_r)/\Gamma$ ,

$$(f,g) = \int_{-\infty}^{\infty} f(x)g(x)dx , \qquad (9)$$

the quantities  $z_{\kappa\lambda}^{(i)}$  in Eq. (6) may be written as

$$z_{\kappa\lambda}^{(i)} = (\pi\delta_i)(f,g^{(i)})/(f,l)(g^{(i)},l)$$
;  $\delta_i = 2E_r(1-\alpha_i)/\Gamma$ , (10)

where

$$g_{\kappa\lambda}^{(i)} = f_{\kappa\lambda} + b^{(i)}h_{\kappa\lambda}$$
 and  $h_{\kappa\lambda}(\xi, x) = \chi(\xi, x)/(\gamma + \psi + \zeta\chi).$  (11)

In Eq. (10),  $\alpha_i = (A_i-1)^2/(A_i+1)^2$ , where  $A_i$  is the mass of either the absorber or the admixed moderator, as measured in neutron masses.

Once the set of IR equations has been solved for the

- 195 -

parameters  $\kappa$  and  $\lambda$ , the resonance integral is determined from Eq. (1). The integral  $J = \frac{1}{2}(f, 1)$  defined in Eq. (3) is the IR generalization of the tabulated temperature-dependent J-function<sup>7</sup>, which includes interference scattering.

Equations (5) and (6) are the generalizations of the IR solution which contain both interference and temperature effects. The coupling between temperature and interference occurs in the integrals contained in the quantity defined as z in Eq. (10). These integrals may be determined from tabulations or may be evaluated numerically. The values of the IR parameters can be determined from Eqs. (5) and (6) by iterative, graphical, or other numerical procedures.

In the extreme WR or NR limits, the solution has the appropriate behavior. In these limits, for example, the physical parameter  $\delta$  in Eq. (10) becomes zero or infinite, so that  $z \rightarrow 0$  (WR) or  $z \rightarrow \infty$  (NR). From Eqs. (5) and (6), this means that  $Z \rightarrow 1$  (WR) or 0 (NR), and the absorber IR parameter  $\lambda \rightarrow 0$  (WR) or 1 (NR), which are the correct limits.

The generalized results also reduce to the previous results when temperature or interference is neglected. For example, when both effects are neglected,  $z \rightarrow \delta/2\beta_{\lambda} = x_{\lambda}$ , and  $\lambda = 1 - (1/x_{\lambda}) \tan^{-1}x_{\lambda}$  (for a one-parameter system). If only temperature is neglected,  $z \rightarrow \delta/2\theta_{\lambda}$ , and if only interference is neglected,  $z \rightarrow \pi \delta K_{\lambda}/2J_{\lambda}^{2}$ , where  $K_{\lambda}=\frac{1}{2}(f,f)$ . All of these results are consistent with earlier solutions of the IR problem.<sup>1-3</sup>

Since the Doppler motion which occurs at non-zero

- 196 -

1.1

temperatures tends to diminish the effect of interference scattering, it is important to evaluate the coupling between interference and temperature. The IR results given by Eqs. (1), (5) and (6) are a consistant set in that both the IR parameters and the resonance integral are functions of temperature and interference, and include the coupling between them. Calculations based on these equations should yield improved Doppler coefficients; at the same time, the need for the semi-empirical fits previously used to account for these effects<sup>5,8</sup>, has been eliminated.

From the form of the IR solutions given, it is possible to make some general observations about the effects of interference scattering on resonance absorption. Consider, for simplicity, a one-parameter system ( $\lambda$  for the absorber). At zero temperature, the increase in absorption due to interference is a function of the magnitude of the ratio  $\omega_{\lambda}/\beta_{\lambda}$ . By evaluating this quantity for a particular resonance and scattering properties, an estimate of the importance of interference scattering can be obtained. Generally, this quantity becomes larger as  $\lambda + 1$  (narrower resonances), and for resonances which have both larger potential scattering ( $\sigma_{p}$ ) and larger resonance scattering  $(\Gamma_{n}/\Gamma + 1)$ . For a given resonance, the interference effect decreases with increasing s; that is to say, it is less important for more dilute systems.

When the temperature is increased from zero, the resonance broadens and the resonance integral increases,

- 197 -

but the effect of interference scattering tends to diminish. Equations (3) and (5) can be used to evaluate the changes in  $\lambda$  and J that occur with varying temperature. Because the representation of the higher energy, more strongly scattering resonances by the IR approximation (rather than the NR approximation) and the inclusion of interference scattering often tend to produce effects which act in the same direction (of increasing the resonance absorption), it is important to evaluate these effects when determining temperature-dependent quantities, especially Doppler coefficients.

Interactive Approaches to Evaluating Methods and Data for Self-Shielded Resonance Absorption<sup>+</sup> Martin Becker Department of Nuclear Engineering Rensselaer Polytechnic Institute Troy, New York 12181

A variety of measurements have been made of self-shielded resonance integrals for  $^{238}$ U. In addition, extensive direct measurements of cross-sections and resonance parameters have been performed. However, when differential data are used to compute the self-shielded resonance integrals, discrepancies of a significant nature arise. As discussed in a number of papers at this symposium, these discrepancies have persisted for some time.

At RPI, considerable experience has built up on interpreting discrepancies between integral measurements and calculations based on differential data, including specific experience with  $^{238}$ U. Most activity has been at moderate to high energies. Thus, resonance integral information has emphasized the unresolved resonance region. However, the approaches used in the unresolved region should also prove useful in the resolved region.

Our experience indicates that there are four ingredients to a program of interpreting integral-differential discrepancies —

(1) The integral measurement must be well defined and of reliable accuracy.

(2) A calculation is available that is sufficiently precise that uncertainty in calculational method can be eliminated as a cause of discrepancy.

(3) A procedure exists for gaining understanding of the sensitivity of the integral quantities of interest to variations in key parameters.

(4) A procedure exists for taking action in translating sensitivity information into specific conclusions and recommendations.

At RPI, fast spectrum activities have emphasized all four ingredients. Well-defined measurements of neutron spectra were performed and analyzed with precise procedures (1,2). In addition simplified analysis (1) based on generalized continuous slowing down theory (3) was used to infer general causes of discrepancies. Most recently, a capability to infer more specific causes of dis-

<sup>+</sup>Sponsored by USERDA under Contract No. AT(11-1)-2458

crepancy has been developed using interactive graphics (4,5). This capability has proved to be quite powerful, and also should be applicable to the low-energy  $^{238}$ U problem and to a variety of other problems.

The interactive capability that has been developed has some unique features that are of particular importance to studying sensitivities. A variety of options useful in the construction of data files to be compared, applying modifications to a data file, calculating and displaying the consequences of these modifications, etc., have been automated through the Rensselaer Interactive Graphics Analysis System (RIGAS). A thirty-two push-button hardware dialogue unit has been constructed to facilitate exercizing these options. In addition, an asynchronous communication capability has been incorporated, permitting time-sharing telephone communication with a CDC-6600 computer for situations where the speed and sophistication of the large computer are required.

The system is designed to separate general file comparison from specific application needs. Specific needs for specific applications are called by a User Routine button. The user by light pen selection picks which routines are to be executed and in which order. These user routines are then used for calculating the implications of modifications introduced into particular files. A new application requires a new set of user routines, but makes use of the automated options that are of general applicability.

Interactive sensitivity evaluation permits comparison of alternate data and of alternate approximations. In the unresolved capture region, for example, relevant comparisons include changes in data from one ENDF/B file to another, and in methodological differences from one processing code to another. The reductions in unresolved capture between ENDF/B-III and ENDF/B-III were found to be appropriate, and the methods in SUPERTOG and MC<sup>2</sup>-II were found to yield equivalent results.

The cross-section file for which the interactive mode has been most useful has been the inelastic scattering file, because of the sensitivity of fast spectra to this file. Interactive modi-

- 201 -

fications have led to a result where the inelastic cross-section is reduced substantially relative to ENDF/B files (6). The result is qualitatively similar in the low MeV range (where the inelastic scattering cross-section reaches a maximum) to the data in the independently-obtained  $^{238}$ U evaluation for the German KEDAK-3 nuclear data library (7).

The interactive approach has the advantage of permitting online exercise of professional judgment. This judgment influences the magnitudes and directions of modifications and influences the consistency among several modifications. It also permits raising and answering important peripheral questions, such as sensitivity of results to uncertainty in relative normalization in files being compared.

It is likely that an approach such as the interactive one would be desirable for dealing with the self-shielded resonance integral over both unresolved and resolved resonances. As reported during this symposium, the integral measurements and the precise calculations leading to the current discrepancy have been reproduced in a number of laboratories for a number of years. A sensitivity evaluation capable of rapid investigation of the significance of a number of detailed possibilities could facilitate focusing on detailed problems, as has been the experience with fast spectra.

EFFECTS OF THE FREE-GAS, SLOWING-DOWN MODEL

ON RESONANCE CROSS SECTIONS IN 238 U\*

R. A. Karam

School of Nuclear Engineering Georgia Institute of Technology Atlanta, Georgia 30332 USA

#### BACKGROUND

Effective resonance cross sections used in the analysis of heterogeneous reactors have generally been obtained through the use of equivalence theory and/or integral transport theory. One fundamentally restrictive assumption common to equivalence theory and most integral transport methods is the flat-flux/flat-source approximation. The assessment of this approximation was recently completed under Contract No. AT-(40-1)-4750 with the U. S. Atomic Energy Commission and reported in ORO-4750-2, December 31, 1974. The assessment comprised the following:

- a. Comparison of the broad group cross sections of <sup>238</sup>U in the resolved resonance region using:
  - 1. The flat-flux/flat-source approximation;
  - 2. The exact source distribution;
  - 3. The rational approximation with Levine type factor. (1)
- b. Comparisons in (a) for three types of reactors:
  - 1. Typical ZPR-assembly;
  - 2. LMFBR commercial power station;
  - 3. Light-water power reactor.

The main conclusions reported in ORO-4750-2 were:

1. Even though there were significant differences between the exactly calculated escape probabilities and those calculated with the flat-flux/ flat-source approximations, additional differences between the general energy dependent reciprocity relation and the energy independent (but often erroneously applied as energy dependent) reciprocity relation almost completely compensated for the error in the flat-flux/flat-source escape

Supported by the U.S. Energy Research and Development Administration under Contract No. AT-(40-1)-4750

probabilities. Due to this unusual and somewhat unexpected compensating effect, the effective capture cross sections of  $^{238}$ U in the resolved resonance region, generated by the three methods stated earlier, were essentially the same (see Table 1).

2. The neutron source, x(r,E), defined as

$$X(\mathbf{r},\mathbf{E}) \approx \int \Sigma_{\mathbf{s}}(\mathbf{r},\mathbf{E}' \rightarrow \mathbf{E}) \boldsymbol{\emptyset}(\mathbf{r},\mathbf{E}') d\mathbf{E}' + Q(\mathbf{r},\mathbf{E}),$$

where the symbols are standard notation, was calculated for the two-region unit cell described in Table 1. The results are shown in Fig. 1 for the 189.6 eV resonance. It is seen that the source in the absorber plate is significantly higher than that in the surrounding medium. The large  $\sigma_p$ of the absorber plate relative to the scattering cross sections of the surrounding medium is the reason why the source is high in the absorber. Under these conditions the resonance integral over the 189.6 eV resonance is largely determined by the source in the plate and not in the surrounding medium.

3. The magnitude of the neutron source shown in Fig. 1 is largely governed by the value of o<sub>p</sub> and the slowing-down process. The slowing-down process used was based on the free-gas model (i.e. the absorber atoms are free in a gaseous state) and on the assumption of isotropic elastic scattering in the center of mass coordinates. The free-gas model, as far as we know, has always been used for neutron energies above 1.0 eV. This is certainly the case in such codes as the MC<sup>2</sup>, RAJBLE, and GAROL.

4. The source distribution shown in Fig. 1 indicates that in order for  $\sigma_c^{238}$  to be too high in the resonance region, either the value of  $\sigma_p$  for  $^{238}$ U would have to be too high or the resonance parameters would have

;

- 207 -

to be too poorly understood, and highly erroneous, or the slowing-down process would have to unrealistically produce large numbers of resonance neutrons. The potential scattering cross section is known to a good accuracy and may be ruled out as a source of major error. The picture with respect to resonance parameters is more complex especially in the unresolved region. However, the magnitude of the differential capture cross section of  $^{238}$ U has been going upward whereas integral measurements required lower values. Whatever the error in the resonance parameter may be, this subject is left to those who measure differential cross sections. In this proposal we concentrate on the slowing-down process and show that the free-gas model for crystalline  $^{238}$ U metal would produce large error in the effective, broad group, resonance capture cross sections of  $^{238}$ U.

#### DISPLACEMENT ENERGY

The minimum energy required to displace an atom from a normal site in the crystal lattice is defined as the displacement energy,  $E_d$ . The value of  $E_d$  may be estimated<sup>(2)</sup> by equating  $E_d$  to the energy of sublimation of an atom in the solid, designated here by  $E_s$ . For uranium,  $E_s \simeq 7.2$  eV; however, sublimation occurs from the surface of a solid, where it is necessary to break only half of the interatomic bonds to move the atom. By comparison, an interior atom has twice as many bonds and thus would require about 14.4 eV for displacement. According to reference (2), if an atom is moved from a lattice site to an interstitial position in the direction of least resistance, allowing time for neighboring atoms to relax, then  $E_d$  would be twice  $E_s$ . In reality, the struck atom receives a sharp blow and passes to an interstitial position in a highly irreversible way.

- 208 -

Consequently, it is estimated (estimates based on experimental data) that the displacement energy is 4-5 times  $E_{\rm c}$ .

The minimum neutron energy required to displace an atom as a function of the atomic weight (taken from ref. 2) is shown in Fig. 2. Although there may be some uncertainty in the value of  $E_{d}$  for uranium it appears that the true value lies somewhere between 30-50 eV. Based on elastic scattering laws, the minimum neutron energy required to displace an atom is given by the following relationship:

$$E_{\min} = \frac{(m_1 + m_2)^2 E_d}{4m_1 m_2}$$

where  $m_1$  and  $m_2$  are the masses of the neutron and the nucleus, respectively. For uranium metal, the minimum neutron energy required to displace atoms lies in the range of 1.8 to 3 keV.

#### PHONON EXCITATION

When the neutron energy is not enough to displace atoms from normal to interstitial sites, the energy loss from the neutron would take place through phonon excitations in the crystal. Based on the Van Hove theory of space time correlations,  $^{(3)}$  the expression relating the phonon emission to the scattering cross section is given by Bell and Glasstone  $^{(4)}$  as

$$\Sigma_{s}(E^{\dagger}) f_{s}(\hat{\Omega}^{\dagger}, E^{\dagger} - \hat{\Omega}, E) = \frac{\Sigma_{b}}{4\pi} \sqrt{\frac{E}{E^{\dagger}}} \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-i\varepsilon t/\hbar}$$
(1)

$$\times \exp\left[\frac{\hbar\kappa^2}{2\text{Am}}\int_{-\infty}^{\infty}\frac{f(\omega)e^{-\hbar\omega/2kT}}{2\omega\sinh(\hbar\omega/2kT)} (e^{-i\omega t}-1)d\omega\right]dt$$

- 209 -

Fig. 2. Displacement Energy vs. Atomic Weight

÷

- 570 -

where

- $\sum_{s}$  = the (macroscopic) bound cross section
- $\varepsilon$  = E'-E the energy transfer from the neutron (initial-final

energy of neutron)

 $\hbar^2 \kappa^2 = 2m (E' + E - 2 \mu_0 \sqrt{EE'})$ 

 $\mu_{o}$  = cosine of the scattering angle (lab system)

- Am = mass of crystal atoms
- K = Boltzmann constant
- T = temperature °K
- $\omega$  = frequency of phonon (in (rad/sec))

t = time (in sec)

This formula is based on the assumption that no interference between different parts of a neutron wave incident on the crystal is present. Furthermore, the crystal is assumed to be of the simple cubic type with one atom per unit cell. The atoms, occupying the lattice positions in the crystal, are assumed to be harmonically bound to each other. Thermalization studies have yielded the phonon distribution function,  $f(\omega)^{(5)}$ , which is shown in Fig. 3. It is obvious from this figure that the primary contribution to the phonon frequency spectrum is due to the two peaks centered at 2.28 x  $10^{13}$  sec<sup>-1</sup> and 3.11 x  $10^{13}$  sec<sup>-1</sup>, respectively. Thus, to a first order approximation it may be assumed that  $f(\omega)$  has the form

$$f(\omega) = 0.39 \ \delta(\omega - 2.28 \ x \ 10^{13} \ sec^{-1}) + 0.61 \ \delta(\omega - 3.11 \ x \ 10^{13} \ sec^{-1})$$

The coefficients of the delta functions appearing in f(w) were chosen in such a way that

- 211 -

Fig. 3. Frequency Spectrum of Uranium

- 212 -

$$\int_{0}^{\infty} f(\omega) d\omega = 1,$$

a normalizing property which  $f(\omega)$  is required to have. An evaluation of Eq. 1 gives a value of 0.041 eV for the maximum energy loss which can occur with 1.5 keV incident neutrons.

The energy loss through phonon excitation is obviously very small and one may choose to either ignore slowing-down in the  $^{238}$ U plate, shown in Table I, or incorporate a fictitious mass in the free-gas, slowing-down model such that the maximum energy loss per collision does not exceed .04 eV. This last approach was tried using the RABBLE code. The atomic mass of  $^{238}$ U was set at 1 x 10<sup>4</sup> amu (corresponding to maximum energy loss of .4 eV), and the capture cross sections in the resolved resonance region, using ENDF/B-III s-wave parameters only, were calculated. For comparison, the same cross sections were calculated in the usual manner, i.e. the mass of  $^{238}$ U was 238 amu's. Table II shows the results. The differences are significant.

It may be argued that for the first two groups the free-gas, slowingdown model may be more appropriate. This may be the case since more work is needed to more accurately determine the displacement energy for uranium. There is no doubt, however, that below 2 keV the free-gas, slowing-down model is not appropriate. Furthermore, large and significant reduction in the  $\sigma_c^{238}$  is achieved with a more appropriate model. Experimentally, it has been observed <sup>(6)</sup> that there are significantly more neutrons below 2 keV than calculations predict. This also supports the conclusion that below 2 keV the scattering laws in use are in error.

#### Technique for Simultaneous Adjustment of Large Nuclear Data Libraries (D. R. Harris and W. B. Wilson) Los Alamos Scientific Laboratory

Successful nuclear design requires adequate prediction of integral design quantities such as critical loading, energy deposition rate, transmutation rate, Rossi-a., and radiation dose. Adequate prediction, in turn, requires an adequate nuclear data base, and a number of groups have attempted to achieve this by adjusting the data base to improve agreement with integral observations. These groups have in all practical cases utilized least square methods<sup>1</sup>, and whatever the functional to be minimized they have limited the adjustment to only a portion of a large nuclear data library. Had the adjustment been applied to another portion of the nuclear data library, another result would have been obtained. The limitation of adjustment to only a portion of the nuclear data library may be justified by physical intuition, but it has also been the result of technical problems in the required inversion of large matrices<sup>1</sup>. We show here that this inversion problem can be circumvented and arbitrarily large nuclear data libraries can be adjusted simultaneous, when, as was assumed by most groups<sup>1</sup>, the basic nuclear data are uncorrelated. We illustrate the technique by adjusting nuclear data to integral observations (including very discrepant central worths) made on the ZPR-6-6A, ZPR-6-7, and ZPR-3-48 fast reactor benchmark critical assemblies<sup>2</sup>.

Group cross sections and other data in a nuclear data library will be represented by  $x_1, x_2, \ldots, x_3$ , where  $\hat{J}$ , the number of primary parameters, may be of order 10<sup>4</sup> or 10<sup>5</sup>. Integral parameters  $y_1, y_2, \ldots, y_4$  are computed as functions of the primary parameters,  $y_1 (x_1, x_2, \ldots, x_3)$ , or  $y_1(x)$  in a convenient notation. Here  $\hat{I}$ , the number of integral parameters usually is of order 10 to 10<sup>2</sup>. From a combination of measurements, corrections, and calculations one arrives at "evaluated" observed values  $x_1^e$ ,  $x_2^e$ ,  $\ldots, x_3^e$ and  $y_1^e$ ,  $y_2^e$ ,  $\ldots, y_4^e$ . It usually is found that  $y_1 (x^e)$  differs from  $y_4^e$  and we wish to reduce this discrepancy. One presumably can improve the data base by minimizing (other techniques are reviewed in Ref. 1),

- 215 -

「まちのからもんい」といれば、それもいます。 これはない いいたいまたい いたのである

$$s = \sum_{i=1}^{j} \sum_{i=1}^{j} w_{y_{i}y_{i}}(y_{i}(x) - y_{i}^{e})[y_{i}(x) - y_{i}^{e}] + \sum_{j=1}^{j} \sum_{j=1}^{j} w_{x_{j}x_{j}}(x_{j} - x_{j}^{e})[x_{j}, - x_{j}^{e}] + 2 \sum_{i=1}^{i} \sum_{j=1}^{i} x_{j}y_{i}[y_{i}(x) - y_{i}^{e}][x_{j} - x_{j}^{e}] , \qquad (1)$$

subject to the requirements that

$$y_{i}(x) = y_{i}(x^{e}) + \sum_{j=1}^{j} \frac{\partial y_{i}}{\partial x_{j}} \Big|_{xe} [x_{j} - x_{j}^{e}] ,$$

$$i = 1, 2, \dots, t , \qquad (2)$$

For minimum variances in the adjusted results the weights w appearing in Eq. (1) are the elements of the inverse of the matrix of variances and covariances among the primary and secondary parameters. The use of a linear relation between y(x) and x in Eq. (2) results because the computation of  $y_i(x)$  and  $\partial y_i/\partial x_j$  is expensive and is done infrequently, although one can of course iterate. We note here that the computation of  $y_i(x)$  and  $\partial y_i/\partial x_j$  (by perturbation theory) is obtained for the whole primary data base at once, not just a portion of it.

If we minimize S by obtaining  $\hat{j}$  normal equations, then the combination of these and the  $\hat{L}$  Eq. (2) represent  $\hat{1}+\hat{j}$  simultaneous equations. In general the normal equations are solved by Gauss-Newton iteration<sup>3</sup>; here as in solution of the simultaneous linear Eqs. (1) and (2) large matrices, at least of order  $\hat{j}\times\hat{j}$ , must be inverted. But if the primary parameters are uncorrelated with each other and with secondary parameters then the normal equations

$$\sum_{i=1}^{1} \sum_{1'=1}^{1} w_{i} y_{i'} [y_{i}(x) - y_{i}^{e}] \frac{\partial y_{i'}}{\partial x_{j}} \Big|_{x_{e}} + w_{x_{j} x_{j}} [x_{j} - x_{j}^{e}] = 0$$

$$j = 1, 2, \dots, j \qquad (3)$$

permit the replacement of  $x_j - x_j^e$  in Eq. (2) by linear combinations of  $y_i(x) - y_{i^*}^e$ . There result only 1 equations for  $y_i(x) - y_{i^*}^e$ .

$$\sum_{i'=1}^{t} [y_{i'}(x) - y_{i'}^{e}] [\delta_{ii'} x \left[ \delta_{ii'} + \sum_{j=1}^{t} \sum_{L''=1}^{t} \frac{w_{L'L''}}{w_{x_{j}x_{j}}} \frac{\partial y_{L''}}{\partial x_{j}} + \sum_{e} \frac{\partial y_{i}}{\partial x_{j}} \right] x_{e} = y_{L}(x^{e}) - y_{i}^{e}$$

$$L = 1, 2, \dots, L$$
(4)

- 216 -

and, because  $\hat{\mathbf{1}}$  usually is much less than  $\hat{\mathbf{j}}$ , the solution of Eq. (4) is a considerable computational improvement. Once the adjusted values  $y_i(\mathbf{x})$  are computed from Eq. (4), the adjusted primary parameters are computed from Eq. (3) for the whole library at once. This adjustment technique has been coded as an option into the ALVIN sensitivity and adjustment code.

We illustrate this improved technique by adjusting nuclear data to  $\hat{1}=24$  integral observations on three ZPR assemblies described by Bohn<sup>3</sup>. Bohn supplies sensitivity coefficient information for only  $\hat{j}=19$  important primary nuclear data parameters so our technique is not really necessary (matrices of order  $\hat{1}+\hat{j}=43$  are readily inverted), but the principle at least is demonstrated. It is convenient to allow  $y_i$  to represent the ratio of the computed value  $C_i$  of an integral parameter to its experimental value  $E_i$ , and to let  $x_j$  represent the ratio of the nuclear datum  $\sigma_j$  to its evaluated value  $\sigma_j^e$ ; then  $y_i^e$  and  $x_j^e$  are unity, and

$$\frac{\partial \mathbf{y}_{\mathbf{i}}}{\partial \mathbf{x}_{\mathbf{j}}} = \left. \begin{pmatrix} \sigma_{\mathbf{j}} & \partial C_{\mathbf{i}} \\ C_{\mathbf{i}} & \partial \sigma_{\mathbf{j}} \end{pmatrix} \right|_{\mathbf{x}\mathbf{e}} = \left. \begin{pmatrix} \sigma_{\mathbf{j}} & \partial E_{\mathbf{j}} \\ E_{\mathbf{i}} & \partial \sigma_{\mathbf{j}} \end{pmatrix} \right|_{\mathbf{x}\mathbf{e}}$$

Specifically, for i=1,2,3 the integral parameters are the C/E values for multiplication factors of ZPR-6-6A, ZPR-6-7, and ZPR-3-48, indicated in the second column of Table I by subscripts A,7, and 8 respectively. For i=4,5,...,15 the integral parameters are the C/E values for central worths of  $^{239}$ Pu,  $^{235}$ U,  $^{238}$ U, and  $^{10}$ B, indicated by 49, 25, 28, and B, respectively as superscripts on W; for example, the C/E value for the central worth of  $^{239}$ Pu in the ZPR-6-7 assembly is indicated by  $W_7^{49}$  in Table I. Finally, for i greater than 15 the integral parameters  $y_i$  are C/E values of ratios of reaction rates, eg,  ${}_7R_{49f}^{28c}$  for  $y_{20}$  represents the C/E value of the  ${}^{238}$ U capture rate relative to the  ${}^{239}$ Pu fission rate measured in ZPR-6-7. If  $y_i$  is  $(\sigma_n/\sigma_m)/(\sigma_n/\sigma_m)$ E, then to first order (unchanged flux spectrum),

$$\frac{\partial y_i}{\partial x_j} \Big|_{xe} = \delta_{nj} - \delta_{mj}$$
.

and the second se

Primary nuclear data selected by Bohn for sensitivity studies are listed in Tables II and III together with sensitivity coefficients computed by Bohn and uncertainties mostly assigned by Bohn. All Bohn's calculations utilize ENDF/B-III data as the evaluated base as processed into multigroup cross sections by SDX. All primary data were assumed to change independent of energy.

Values of primary and secondary parameters adjusted by ALVIN are listed in Tables I and III and show physically expected trends. Values selected by Bohn on the basis of the integral experiments also are listed. Our data adjustments are only illustrative of our adjustment technique. More detailed study of data uncertainties and sensitivities would be required to justify an adjusted data set for nuclear design application.

#### ENDF/B-IV THERMAL REACTOR LATTICE BENCHMARK

## ANALYSIS WITH MONTE CARLO RESONANCE TREATMENT

W. Rothenstein Brockhaven National Laboratory Upton, New York 11973

1. Introduction

The benchmark studies currently in progress at ENL are based on ENDF/B-IV data and the HAMMER lattice analysis code.<sup>(1)</sup> No data adjustments are made, but improvements are introduced into the calculational procedure wherever appropriate. In particular the resonance treatment is replaced by Monte Carlo reaction rates, attention being given to the most effective manner in which these reaction rates can be introduced into the multigroup code.

The multigroup library has been prepared in accordance with the special features of the subsequent heterogeneity, resonance, and leakage treatments. The problems which arise from the artificial separation of resonance cross sections into resonance and smooth contributions have been investigated. An account is given of the modifications which have been introduced into the processing code in order to derive the required ENDF/B-IV multigroup data.

The benchmark lattices analyzed and described in the present paper are the one region TRX-1 and TRX-2 lattices<sup>(2)</sup> of 1.3% enriched, 0.387 inch diameter Uranium metal rods. In order to extend the range of volume ratios the two region TRX-3 benchmark has been replaced by a  $\text{ENL}^{(3)}$  lattice containing the same fuel and with the same water to metal volume ratio. It will be denoted by TRX-3B, and is calculated as a one region system with the experimental buckling of the ENL lattice. The other integral parameters were taken from TRX-3, where they were measured at the center of the lattice. It contained 217 rods and was surrounded by a  $UO_2-H_2O$  driver zone.

- 222 -

1 -

The Monte Carlo code for the calculation of resonance events will be described. It makes use of ENDF/B-IV resonance profiles which are stored on tapes in standard ENDF/B format so that they can be readily replaced if modifications in the evaluated data are considered to be necessary. The code concentrates on the resolved resonance region in which most of the resonance absorption occurs. At these energies, the Monte Carlo results are used in the lattice analysis code in preference to the built in calculation of shielded resonance integrals. In the unresolved resonance region the shielding is considerably smaller and the absorption represents only a small fraction of the total resonance absorption. Consequently, the shielding calculations in the unresolved resonance region have been left unmodified in the lattice analysis. On the other hand, it is possible to introduce the effective detailed resonance profiles into the Monte Carlo code by the use of probability cables. A simple code for constructing such tables from the single level ENDF/B average resonance parameters and statistical distributions in the unresolved resonance region is described in the Appendix. The results obtained by this code have shown that cross section correlations in the unresolved resonance region at successive neutron energies during the moderating process can be ignored.

The paper contains the results of the analysis of the TRX lattices together with the effects of a number of different approximations which can be used in the calculations. The final results and conclusions take into account the discussions held at BNL during the seminar on U-238 capture in March 1975.

In general, the effective multiplication factor of the lattices is still underpredicted, but the other integral parameters are now closer to the experimental values than was frequently reported in the past.

- 223 -

## 2. Monte Carlo Code for Resonance Reaction Rates

The Monte Carlo Code (REPC) which was used to calculate resonance reaction rates utilizes detailed resonance cross section profiles prepared by the RESEND program<sup>(4)</sup> from the ENDF/B-IV data.

RESEND replaces the standard ENDF/B tape by a modified library in which the File 2 resonance parameters are deleted and File 3 is extended to contain the detailed cross sections as a function of energy at 0°K throughout the resonance region. The resonance formalisms as recommended in the ENDF/B manual<sup>(5)</sup> are fully implemented. In the resolved resonance region the energy mesh is constructed by selecting initially the energies of the resonance peaks and successively halving the interval between them until an interpolation accuracy criterion e is met: the fractional difference between the cross sections calculated from the resonance formalism at the mesh points selected last and the value obtained by linear interpolation between the neighboring points must not exceed c. For U-235 and U-238 the accuracy was taken to be  $\varepsilon$  = 0.001. The sections for  $\sigma_{g}^{}, \sigma_{f}^{}, \sigma_{c}^{}$  of the former then contained about 11000 energy points each (most of these points being in the resolved resonance region between 1.0 and 82.0 ev), while for U-238 the cross sections  $\sigma_s$  and  $\sigma_c$  were specified at about 32000 energies (most of the points being between 1.0 and 4000 ev).

The cross section tapes were subsequently Doppler broadened by the SIGMA 1<sup>(6)</sup>routine. This procedure does not alter the energy mesh, and makes use of the integrals of the product of the (linearly varying) cross section between successive energy points and the Gaussian temperature broadening kernel.

- 224 -

To facilitate the data handling in the Monte Carlo code the sections specifying the different cross sections of each isotope are brought to a common grid (in practice the densest grid), so that the energy mesh needs to be stored only once for each isotope. In addition the grids were inverted so that the cross sections could be read from high to low energy in analogy with the neutron moderation.

In the Monte Carlo code the cross section data are stored in the extended core facility of the CDC 7600. The neutron histories are dealt with in batches (typically of 1000 neutrons each). Part of the data (a page with lowest energy  $E_L^i$ ) for each nuclide *i* is transferred to central memory, and the entire neutron batch is processed until all the neutrons have reached an energy below the largest  $E_L^i$  stored in the core. A new page of data for this isotope *i* now read into central memory and the process is repeated until all the neutrons in the batch have passed the minimum energy specified for the problem.

In the unresolved resonance region the RESEND program calculates average cross sections from the specified average resonance parameters and statistical distributions. Resonance shielding is therefore not treated at these energies in a Monte Carlo code which uses the broadened RESEND cross section tapes directly. It is possible however to make use of the probability table method<sup>(7)</sup> to modify the cross sections in the unresolved resonance region. The construction of the proability tables from the average resonance parameters and statistical distributions is quite straightforward when the single level resonance formalism applies. In the Appendix a code written for this purpose is described. It averages the probability tables

- 225 -

over many ladders. The code has been used to investigate the significance of correlations between cross sections at relatively closely spaced energy points which would be missed by the direct use of uncorrelated probability tables. It was found that for energy degradations greater than the average separation of successive resonances such correlations are entirely negligible. This condition is met for practically all neutron collisions with heavy isotopes in the energy regions where their resonances are unresolved.

The Monte Carlo Code(REPC) itself is a new version of the REPETITIOUS program<sup>(8)</sup>. It treats the geometry of a square or hexagonal lattice of rods, each subdivided into a number of coaxial annular regions, exactly. The neutron histories are followed between energies E and E in which all collisions are taken to be elastic and isotropic in the center of mass system. These conditions apply in the entire resolved and most of the unresolved energy regions. The isotropic injection routine introduces each neutron into the lattice with unit weight at the first energy with which it emerges below  $E_{max}$  after an elastic collision above this energy, assuming that the cell flux is proportional to 1/E for  $E > E_{max}$ . The neutron weight is degraded by the scattering probability  $\Sigma_s / \Sigma_t$  at each collision, reaction rates being obtained from  $W \sum_{x} / Z_{t}$  for the different reaction types x. For editing purposes the reaction rates are stored by regions in specified energy groups, which may be conveniently selected to coincide with the MUFT group structure. All quantities are printed out together with their probable errors at one standard deviation obtained from the results for the different batches.

- 226 -

1.

In the calculations reported in the present paper the Monte Carlo runs covered the energies from  $E_{max} = 50$  kev, to  $E_{min} = 0.625$  ev, and used the Doppler broadened RESEND tapes. The Monte Carlo reaction rates were utilized only in the resolved resonance region which accounts for most of the resonance capture and fission, and where a precise determination of the shielding effect is most important. The resolved resonance region is sufficiently far below the source near  $E_{max}$  for the results to be independent of any small approximations made in the injection routine. For the resonance reaction rates in the unresolved resonance region the standard routines in the lattice analysis code were regarded as adequate, since they are much smaller than those at lower energies, and far less affected by shielding.

A basic problem exists in the use of the cross section tapes constructed with the Breit Wigner single level resonance formalism in a Monte Carlo code. The current ENDF specifications<sup>(5)</sup>do not lead to cross sections which are positive definite. The problem of negative scattering (and sometimes total) cross sections over limited energy ranges below some resonance peaks persists even after Doppler broadening. In the Monte Carlo code  $\sigma_s$ was set to zero whenever a negative value was encountered. Alternative libraries in which the isotopes were treated by the multilevel formalism, but without changing any of the resonance parameters, were also used; the problem of negative cross sections was then automatically eliminated. The effect of the different formalisms for the calculation of  $\sigma_s$  on the resonance reaction rates was investigated, and found to be very small (see paragraph 7).

- 227 -

## 3. Shielded Resonance Integrals and Resonance Reaction Rates

Different computational methods treat the resonance events by methods which are quite distinct from one another. A Monte Carlo program for example calculates the resonance reaction rates directly. They can be recorded by reaction type, by nuclide giving rise to the reaction under consideration, and in specified volumes and energy intervals. They are generally normalized to one source neutron. These reaction rates are part of those needed to specify the neutron balance in a reactor or a lattice unit cell.

Other programs such as the HAMMER lattice analysis code perform a calculation of the shielded resonance integral which must be subsequently translated into resonance reaction rates. If one treatment of the resonance region is to be substituted for another to improve the accuracy of the lattice analysis, care must be taken that the interface is handled properly.

In the HAMMER program the shielded resonance integrals are obtained from Nordheim's method<sup>(8)</sup>. Inherent in this treatment are a number of approximations<sup>(9)</sup> which make its replacement by more precise calculations desirable. However, apart from these considerations the manner in which the Nordheim shielded resonance integrals are used in the lattice analysis code must be clarified, if this calculation is to be replaced by an alternative treatment. The calculation of the shielded resonance integral for the nth resonance is based on the relation between the collision density  $F_n(u)$ at lethargy u in the resonance and the flux level  $\phi_n$  in the absence of flux depression:

- 228 -

自己のなどの自己なないので、

$$F_{n}(u) = \Sigma_{t}^{n}(u) \phi(u) = N \sigma_{B} \phi_{n}$$
(1)

when N  $\sigma_{\rm B}$  is the constant macroscopic background cross section. The absorption in the resonance is then given by:

$$A_{n} = \int_{n} \frac{\sum_{a}^{n} (u)}{\sum_{t}^{n} (u)} F_{n}^{(u)} du = N I_{eff}^{n} \phi_{n}$$
(2)

so that

$$I_{eff}^{n} = \int_{n} \frac{\Sigma_{a}^{n}(u)}{\Sigma_{t}^{n}(u)} f_{n}(u) du$$
 (3)

where  $f_n(u)$  is the collision density normalized to  $c_B$  above the resonance. In Nordheim's method  $f_n(u)$  is calculated for a lattice cell by solving the integral equation for the collision density ...umerically over a very fine mesh starting at a lethargy where the asymptotic value applies. Cell heterogeneity is taken into account by the use of region to region collision and escape probabilities. The absorption fraction in the nth reseonance is

$$\alpha_{n} = \frac{A_{n}}{q_{o}} = \frac{N I_{eff}^{n} \phi_{n}}{q_{o}}$$
(4)

where  $q_0$  is the slowing down source into the group in which the resonance lies. If one allows for the gradual decrease of the flux level due to absorption (but without depression due to the resonance)

$$\alpha_n = 1 - \exp\left(-\frac{N \prod_{eff}^n \phi_n}{q_o}\right) \text{ and } \alpha_g = \sum_n \alpha_n$$
 (5)

- 229 -

あるというないのというできるなななななないである

The total absorption fraction  $\alpha_g$  per unit source into group g, obtained by replacing the  $\phi_n$  in Eq. 5 by the average group flux  $\phi_g$ , forms the basis of the resonance absorption treatment in the HAMMER lattice analysis code.

The resonance treatment may be replaced by a Monte Carlo calculation by correcting the resonance integrals of Eq. 3. In fact, this has frequently been done in the past. A shielded resonance integral may be calculated from the Monte Carlo resonance events by means of the group resonance escape probability

$$P_{g} = \exp\left[-\frac{N I_{eff}^{B}}{5\Sigma_{B}}\right]$$
(6)

This value of  $I_{eff}^{g}$  is based on the volume averaged slowing down powers of all the constituent nuclides of the lattice cell for a flat flux. On the other hand in Eq.3  $I_{eff}$  results from the (potential) scattering cross section  $\sigma_{B}$  of the fuel with its admixed nuclides, which is the asymptytic value of the collision density, as well as from collision probabilities calculated by suitable approximations. Whether the two definitions  $o \in I_{eff}^{g}$  are identical in practice is by no means certain.

For the reasons stated above the reaction fractions  $a_g^x$  per unit source into the group for each reaction type x, which are calculated directly in a Monte Carlo code, were preferred to the shielded resonance integrals as the interface for introducing the Monte Carlo results into the lattice analysis code. Even so, questions arise whether this should be done in the integral transport theory lattice heterogeneity calculation, or as a preliminary to the B-1 leakage calculation. In addition there are problems connected with the separation of smooth and resonance absorption. These points will be considered in Section 5.

#### 4. Preparation of the Multigroup Libraries

The ENDF/B-IV epithermal multigroup library was obtained with the ETOG 3 rpocessing code<sup>(11)</sup>. A number of modifications were introduced for consistency with the HAMMER analysis code<sup>(1)</sup>. The additional options refer in particular to the resonance nuclides. They will be described with special reference to the options selected for U-235 and U-238.

The MUFT 54 epithermal group structure was used with thermal cut off at  $E_c = 0.6248$  ev. The weighting function was a 1/E spectrum joined above  $E = 6.738 \times 10^4$  ev (the low energy limit of group 20) to a simple fission spectrum  $[4E/(TH\theta^3)]^{\frac{1}{2}} \exp(-E/\theta)$ , with  $\theta = 1.323$  MeV in accordance with U-235 thermal fissions (ENDF/B-IV).

Equivalent smooth unshielded capture and fission cross sections can be constructed from the specified resonance parameters in the ENDF/B library. Alternatively the resolved s wave resonance parameters can be included in the input to the HAMMER analysis code in which case they are not entered as smooth cross sections into the multigroup library. If this option is selected one may additionally treat the unresolved s wave resonances in the same way provided they lead to only one J state of the compound nucleus; otherwise they are converted to equivalent unshielded smooth cross sections. For any resolved resonance for which resonance shielding is calculated in the HAMMER code a 1/v tail is subtracted from the resonance integral. It is put back as a smooth cross section in each group g in the resolved resonance region, down to the low energy limit of this region. These 1/v smooth tail contributions are calculated for a 2200 m/sec cross section

- 231 -

 $\sum_{c_{o}}^{R} \frac{\Gamma_{x}}{\Gamma} \sqrt{\frac{E_{R}}{E_{th}}} \left( \frac{4}{\Gamma^{2}} (E_{R} - E_{th})^{2} \right)$ 

for resonance R and reaction type x and assuming a 1/E flux in each resonance group for cross section weighting. The resolved resonance region is taken to end at the upper energy of the multigroup just below the unresolved resonance region, and a similar choice is made at the upper end of the latter region.

For U-235 only the resolved s wave resonance parameters were kept for resonance shielding calculations in HAMMER. All other resonances were converted to smooth unshielded cross sections. For U-238 the resolved and unresolved s wave resonance parameters formed part of the HAMMER input; the p wave resonances were converted to smooth cross sections. A separate calculation of the small unresolved p-wave resonance shielding was made in this case and entered into the lattice analyses as a correction. In the resonance region resonance scattering was omitted from the multigroup library since it is included in the resonance absorption calculation.

The (n,2n) cross section was added twice to the inelastic-scattering cross section and subtracted once from the capture cross section. Assuming that the spectra of the neutrons after inelastic scattering and the (n,2n)reactions are not very different this procedure accounts for the additional neutrons which are produced and preserves neutron balance in the group in which the reactions occur.

- 232 -

An error in the calculation of the fission spectrum in the ETOG 3 code was noticed and corrected. The original calculations had altered the shape of the fission spectrum very slightly and led to high values of the fast fissions in U-238 in the lattice analyses reported during the U-238 resonance capture seminar. The results given in the present paper are based on the corrected U-235 fission spectrum.

The thermal 30 group multigroup libraries for THERMOS were produced with the FLANGE-II code (12) which was also used to calculate the scattering kernels (10) for the thermal spectrum calculations. Whenever the resonance region extends into the thermal energy range, resonance scattering was included in the preparation of the thermal libraries. The thermal scattering kernels were normalized to the inelastic cross section, or the sum of inelastic and elastic scattering, according to the data specified on the ENDF/B tapes for each moderator.

#### 5. The HAMMER Lattice Analysis Code

The HAMMER lattice analysis, including a full account of the equations involved, has been described previously<sup>(10)</sup>. In the present section only a broad outline will be given together with details of some problems which arise in the resonance treatment.

The calculations are performed in accordance with the following flow chart:

- 233 -

# HAMMER LATTICE ANALYSIS

Few Group Parameters Reaction Rates

Keff

. .....

1.1

, maximum (max), nt pt (max). ● The lattice analysis starts with the THERMOS thermal spectrum calculation for which a spatially flat flux can be assumed for the specification of the slowing down source. In fact apart from resonance shielding the cell flux is flat already at considerably higher energies.

The integral transport treatment for the calculation of the neterogeneity effects is based on the iterative solution of the transport equation for the scalar flux

$$\phi_{ni} = \sum_{n', n'} \left[ \sum_{j} P_{n'ij} \phi_{n'j} + S_{n'i} \right]$$
(7)

Here  $T_{n n'i}$  is the transport kernel from region n' to region n in group i. It is related to the collision probability  $p_{n n'i}$  in n for a flat source of unit density in n' through

$$T_{n \alpha' i} = \frac{\sum_{n \alpha' i}^{n \alpha' i}}{\sum_{n i}^{n \alpha} v_{n \alpha'}}, \quad \sum_{n \alpha' \alpha' i}^{n \alpha' i} = V_{\alpha'}$$
(8)

in which  $\Sigma_{ni}$  is the transport corrected total cross section. In the thermal energy range  $P_{n'ij}$  is the transport corrected scattering kernel from group j to group i and  $S_{n'i}$  is the elastic slowing down source from epithermal energies into thermal group i. At epithermal energies  $P_{n'ij}$  is replaced by the in-group scattering kernel  $P_{n'i}$  and the source includes elastic and inelastic scattering into group i as well as the fission contribution.

Some of the problems which arise in the presence of both smooth and resonance absorp ion in the epithermal energy groups may be seen if one specifies the source term and in-group scattering kernel in the resonance region, where the sources due to fission and inelastic scattering are absent. Considering the entire cell and assuming all parameters to be suitably cell averaged the slowing down density q(u) satisfies the approximate Greuling Goertzel integral equation<sup>(13)</sup>

$$q = \frac{\xi}{\lambda} \int_{-\infty}^{u} e^{-\frac{(u-u')}{\lambda}} \Sigma_{s}(u') \phi(u') du'$$
(9)

where  $\xi$  and  $\xi_{\lambda}$  are the mean and half the mean square lethargy increments for an elastic collision. For hydrogen moderation this equation is enact and  $\xi = \lambda = 1$ . If the corresponding differential equation

$$\mathbf{q} + \lambda \quad \frac{\mathrm{d}\mathbf{q}}{\mathrm{d}\mathbf{u}} = \xi \Sigma_{\mathbf{s}} \phi \tag{10}$$

is integrated over an energy group in which  $\boldsymbol{q}_{0}$  and  $\boldsymbol{q}_{1}$  refer to the high and low energy limits

$$q_{1} = q_{0} \frac{\lambda - \frac{\Delta u}{2}}{\lambda + \frac{\Delta u}{2}} + \frac{\xi \Sigma_{s} \phi \Delta u}{\lambda + \frac{\Delta u}{2}}$$
(11)

in which  $\lambda,\ \xi\ \Sigma_{g}$  and  $\phi$  are now group averages.

The neutron balance equation

$$\Sigma_{a}\phi = \frac{q_{o} - q_{1}}{\Delta u} = \frac{q_{o}}{\lambda + \frac{\Delta u}{2}} - \frac{\xi \Sigma_{s}\phi}{\lambda + \frac{\Delta u}{2}}.$$
 (12)

or

$$\Sigma_{tr} \phi = P\phi + S$$
,  $\Sigma_{tr} = \Sigma_{s,tr} + \Sigma_{a}$  (13)

is now fully consistent with the transport equation, Eq. 7, summed over the entire cell after multiplying by  $\Sigma_n V_n$ , if

$$\mathbf{P} = \Sigma_{s,tr} - \frac{\xi \Sigma_s}{\lambda + \frac{\Delta u}{2}} \quad \text{and} \quad \mathbf{S} = \frac{\mathbf{q}_0}{\lambda + \frac{\Delta u}{2}} \tag{14}$$

and the second 
The absorption cross section in Eqs. 12 and 13 refers to the smooth absorption. Resonance absorption can be allowed for in different ways. The simplest method consists of accounting for it immediately at the top of the group by replacing  $q_0$  in Eqs. 11, 12, and 14 by  $q_0$  (1- $\alpha$ ) where  $\alpha$  is the resonance absorption per unit slowing down density at the top of the energy group, as calculated in Section 3. Neutron balance is then still preserved. This is in fact the MUFT procedure. The group flux calculated from Eq. 7 is then depressed both by smooth and by resonance absorption. Such a procedure would require calculating a first, before the source for the solution of the integral transport problem, Eq. 7, is specified. On the other hand, the current version of the HAMMER makes use of the flux distribution in the lattice cell in order to specify the collision probabilities which are needed for the calculation of  $\alpha$ . An iterative procedure between the resonance and transport calculations would then be necessary. At present the iteration is omitted in the HAMMER code by solving the integral transport problem first, calculating a subsequently, and allowing for the resonance absorption only in the calculation of  $q_1$  by using  $q_0(1-\alpha)$  in Eq. 11. The source S =  $q_0 / (\lambda + \frac{\Delta u}{2})$  is not reduced to allow for resonance absorption in the group in which the transport equation, Eq. 7, is solved. Neutron balance is therefore violated.

- 237 -

These difficulties do not arise in the B-1 leakage calculations for the homogenized lattice cell. Here the neutron balance equation for buckling B is

$$(BJ + \Sigma_a \phi) \, \omega u + q_o \alpha = q_o - q_1 \tag{15}$$

below the fission source and in the absence of inelastic-scattering. It is solved together with the isotropic slowing down equation, Eq. 10, the B-1 equation for the current, and the anisotropic slowing down equation. If Eq. 11 is used to eliminate  $q_1$  from Eq. 15 it is clear that the resulting relation between  $q_0$  and the flux depends on the leakage. Consequently, in expressing the resonance absorption as a fraction of  $q_0$ , at the high energy limit of an energy group,  $q_0$  should be corrected for leakage. This is in fact done in MUFT-5<sup>(14)</sup> but not in the current version of HAMMER. On the other hand the average group flux is the flux in the presence of leakage.

In the light of these considerations and the discussions during the U-238 resonance capture seminar the Monte Carlo resonance reaction rates (smooth and resonance) in the resolved resonance region were introduced into HAMMER code just before the leakage calculation for the homogenized cell. In fact, group capture and fission cross sections were defined (iteratively) in a zero buckling homogenized cell calculation so that the Monte Carlo group capture and fission rates, suitably normalized, were reproduced exactly. The effective multiplication factor and integral parameters were then obtained after the subsequent B-1 leakage calculation. In addition to the resonance shielding the reduction of the smooth capture due to flux depressions near the resonance peaks, as well as the effect of leakage on the total absorption,

- 238 -

were thus fully taken into account.

An additional consideration regarding the slowing down treatment refers to the heavy isotopes. If the slowing down and neutron balance equations, Eqs. 11 and 12, are solved for  $q_1$  at the low energy limit of an energy group,

$$q_{1} = \frac{\xi \Sigma_{s} + \Sigma_{a} (\lambda - \frac{\Delta u}{2})}{\xi \Sigma_{s} + \Sigma_{a} (\lambda + \frac{\Delta u}{2})} q_{o}$$
(16)

a caracteristics and

When  $-u \gg \lambda$  spurious reductions in the slowing down density may occur. These can be avoided by setting  $\lambda = \frac{-\lambda u}{2}$  so that

$$\phi = \frac{q_1}{\xi \Sigma_s + \Sigma_a (\lambda - \frac{\Delta u}{2})} \rightarrow \frac{q_1}{\xi \Sigma_s}$$
(17)

which implies that the contribution to  $q_1$  from the heavy isotopes is based, approximately, on the average group flux.

# 6. Effective Capture Integrals of U-238 in the TRX Lattices

The separation of the U-238 capture into smooth and resonance contributions, and the importance of shielding corrections may be seen from the following tables.

U-238 Capture Integrals (barns) Treated as Smooth Capture

L/V Tails of resolved S wave resonance	0.79
-wave resolved resonances	0.70
p-wave unresolved resonances	0.84
File 3 Capture	0.33
Total	2,65

- 239 -

ŝ,

U-238 Shielded S Wave Resonance Integrals (barns)

	TRX-3B	<u>TRX-1</u>	TRX-2
Resolved Resonance			
Region	10.35	11.84	12.35
Unresolved Resonance			
Region	0.55	0.58	0.59
Total	10.90	12.42	12.94

# Reduction of U-238 Resonance Integrals Due to Shielding (barns)

	TRX-38	TRX-1	TRX-2
Resolved s Wave Resonances	260.7	259.2	258.7
Unresolved <sup>s</sup> Wave Resonances	0.24	0.22	0.21
Unresolved p wave resonances	0.06	0.05	0.05

The File 3 capture consists of a bound level contribution, p -wave resonances which were missed in the experiments, and a small d-wave resonance contribution in the unresolved resonance region.

It should be noted that more than twenty percent of the capture is treated as smooth capture and therefore does not get reduced by local flux depressions at energies close to the resonance peaks unless codes, such as Monte Carlo treatments, are used which combine smooth and resonance capture.

The s wave resolved resonances are shielded to an extremely large extent. This is particularly true for the very large low lying resonances. Unresolved resonance shielding is far less important, but even so in terms of the effective unresolved resonance integral, or even the total effective resonance integral, these shielding corrections must be taken into account.

- 240 -

1.1

# 7. Effect of Different Resonance Formalisms on U-238 Resonance Capture

In Section 2 the problems arising in Monte Carlo calculations from the use of the single level Breit Wigner formalism were discussed. In addition even a multi-level formalism does not reproduce the experimental data of the total cross section in the valleys between the resonance peaks very well. Typically the  $\sigma_t$  profile should be raised by about 2 barns in these energy regions. In order to examine the effect of the detailed shape of  $\sigma_s$  on the capture in the benchmark lattices the Monte Carlo calculations for TRX-1 were repeated under different conditions. In the following table the results are shown both for the shielded resonance integral and the capture fraction between 50 kev and 0.625 ev.

# TRX-1 Monte Carlo U-238 Resonance Capture $E_{max} = 5 \times 10^4 \text{ ev}, \quad E_{min} = 0.625 \text{ ev}$

Resonance Treatment	Resonance Integral(barns)	Capture Fraction
Single level (o <sub>s</sub> ) <sub>min</sub> = 0.0	14.97 ± 0.08	0.1929 ± 0.0008
Single level (c <sub>s</sub> ) <sub>min</sub> = 2.0	15.16 ± 0.15	$0.1951 \pm 0.0017$
$\sigma'_{s} = \sigma_{s} + 2.0$		
for $6.67 < E < 4000$ ev	14.99 ± 0.07	$0.1932 \pm 0.0008$
Multilevel	$14.84 \pm 0.08$	$0.1918 \pm 0.0008$

The minimum acceptable value of  $\sigma_s$  is 0. In the second calculation  $\sigma_s$  was set equal to 2.0 barns whenever a smaller value was obtained from the ENDF/B-IV profile. In the third calculation 2.0 barns were added to  $\sigma_e$  at all energies in the resolved resonance region above the first resonance.

- 241 -

and a second second

The last result relates to a multilevel profile in which the ENDF/B-IV single level parameters were left unchanged. All the results except the second were obtained for  $10^5$  histories involving about 1.2 x  $10^6$  moderator and 2.4 x  $10^5$  fuel collisions. In the second calculation only 20000 histories were run.

It is clear that the different shapes of  $\sigma_s$  in the valleys did not affect the U-238 capture by an amount exceeding the probable error at one standard deviation. The use of the ENDF/B-IV profile, in which  $\sigma_s$  is not allowed to become negative, appears therefore to be adequate.

The Monte Carlo estimate of the U-238 reaction rate was compared with a RECAP calculation made at Westinghouse with ENDF/B-IV data by J. Hardy. The results agreed within the statistical accuracy of both estimates.

# Comparison of Resonance Shielding Calculations With Monte Carlo Estimates

The shielded resonance integrals as calculated by the HAMMER program can be compared with Monte Carlo values although part of the differences may arise from problems of definition of the shielded resonance integral as pointed out in Section 3.

Comparison of Shielded Reso	nance Absorption	Integrals in the	TRX Lattices
U-238 (1.0 ev '- 3.35 Kev);	U-235 (1.0 ev -	101 ev)	(barns)
	TRX-3B	TRX-1	<u>TRX-2</u>
U-238 HAMMER M.C.	10.35 9.65 ± 0.09	11.84 11.42 ± 0.11	12.35 11.87 ± 0.11
U-235 HAMMER M.C.	208.3 177.7 ± 1.8	218.1 194.5 ± 1.9	220.9 201.6 ± 2.0

- 242 -

The values refer to the groups which were treated as resolved resonance groups, MUFT groups 27-53 for U-238, and 35-53 for U-235. The Monte Carlo values given in the table are those obtained after subtraction of the smooth absorption integral of the HAMMER library in the resolved resonance groups. This ensures that similar quantities are compared. The Monte Carlo values are lower by about 5 percent in U-238 and more than 10 percent for U-235.

Comparisons of the total reaction rates (smooth and resonance) are tabulated below:

# Comparison of Reaction Rates in the TRX Lattices U-238 (1.0 ev - 3.35 Kev); U-235 (1.0 ev - 101 ev)

		TRX-3B	TRX-1	TRX-2
บ-238	HAMMER	0.2841	0.1640	0.1065
	Corrected HAMMER	0.2560	0.1552	0.1029
	M.C.	$0.258 \pm 0.003$	$0.155 \pm 0.002$	$0.1015 \pm 0.001$
<b>v-23</b> 5	Capture			
	HAMMER	0.0267	0,0148	0.00952
	Corrected HAMMER	0,0242	0.0141	0,00924
	M.C.	$0.0210 \pm 0.0002$	$0.0123 \pm 0.0002$	$0.00817 \pm 0.0001$
V-235	Fission			
	HAMMER	0.0478	0.0264	0.0169
	Corrected HAMMER	0.0435	0.0252	0.0164
	M.C.	$0.0401 \pm 0.004$	$0.0235 \pm 0.0003$	$0.0154 \pm 0.0002$

The corrected HAMMER values refer to the neutron balance in the integral transport calculation (see Section 5). The resonance reaction fraction per unit slowing down density at the top of each energy group is calculated in the code in relation to the group flux. This flux is calculated in the absence of resonance absorption and there is a lack of balance of the neutrons. The correction discussed in Section 3 ensures neutron balance and lowers the group

- 243 -

flux in accordance with the total absorptions occurring in the group. Consequently, the reaction rates are also lowered.

The table shows that the differences between the Nordheim and Monte Carlo calculations for the U-238 caputre in the TRX lattices is largely eliminated if the integral transport theory neutron balance is treated as described in Section 5. This is however fortuitous. In the corrected HAMMER results smooth capture is calculated more accurately, but resonance capture is underestimated since it should refer to the group flux level in the absence of the resonances. Evidently the underestimate is just sufficient to compensate for the inaccuracies in the Nordheim treatment. Other methods for treating resonance capture in the integral transport calculation with proper neutron balance may be used. The resonances could be accounted for at the bottom of each group, so that smooth absorption would be overestimated but resonance absorption treated in accordance with Section 3. Alternatively, two flux levels could be calculated, the first based on the smooth absorption only to derive the proper resonance absorptions in the presence of the resonances.

The Monte Carlo absorption rates are unambiguous since resonance and smooth data are combined at the outset in the cross section calculations. They also account for mutual shielding, in particular the reduction of the U-235 absorptions in the vicinity of the large U-238 resonances.

9. keff and Integral Parameters of TRX Lattices (HAMMER, ENDF/B-IV)

The corrections referred to in the previous section improve the agreement between the HAMMER calculations and experimental values. The quantities compared are the effective multiplication factor  $k_{eff}$ , the ratio of epithermal to thermal captures in U-238  $\rho_{28}$ , the ratio of epithermal to thermal fissions in U-235  $\delta_{25}$ , the ratio of U-238 fissions to U-235 fissions  $\delta_{28}$ , and the ratio of U-238 captures to U-235 fissions C.

Comparison of Integral Parameters for the TRX Lattices (ENDF/B-IV, HAMMER)

The extent by which  $k_{eff}$  differs from unity is large for the tightest lattice (water to metal volume ratio 1.0). The correction described in Sections 5 and 9 have the most pronounced effect on  $k_{eff}$  for this lattice. The correction improves agreement between calculation and experiment for all the integral parameters of the above lattices.

10. TRX Benchmark Analysis With Monte Carlo Reaction Rates

The Monte Carlo reaction rates were introduced into the HAMMER analysis at zero buckling after the lattices had been homogenized by defining group fission and capture cross sections as described in Section 5. The effect of leakage was then introduced in a final iteration.

1.20

The results are compared with experiment in the following table.

.

An attempt was made to attribute the remaining discrepancy between calculation and experiment to the U-238 capture data. The calculations were repeated by subtracting 0.1 barns from the group capture cross section throughout the resolved resonance region. This amounts to a capture integral of 0.83 barns.

The results for the integral parameters  $\rho_{28}$  and C suggest that a reduction of the U-238 shielded resonance integral by about 0.4 barns would lead to the best overall agreement with experiment.

#### 11. Further Refinements and Conclusions

The results for the TRX benchmarks presented in this paper suggest that the epithermal capture of U-238 is overpredicted to some extent by the present ENDF/B-IV data. However, the discrepancy is smaller than was reported in the past and amounts approximately to 0.4 barns of shielded resonance integral.

The  $k_{eff}$  values are generally low and specially so for the tightest lattice, even if the data for U-238 are adjusted as indicated above. An attempt was made to determine whether some of this problem might be due to the calculations in the fast region where the fission neutrons are produced in the rods. To this end the calculations were repeated with corrected fluxes in the high energy groups using the ANISN<sup>(15)</sup> transport code.

Fluxes entered into the HAMMER calculation from a P1-S4 ANISN run for the highest 20 energy groups (down to 67 kev), or P3-S8 ANISN run for the highest 10 energy groups (down to 820 kev) did not lead to a noticeable change in the calculated parameters. In fact, the ANISN flux distributions

- 247 -

in space and energy in these groups were practically identical with the HAMMER integral transport fluxes.

An additional effect which was examined in the final MUFT leakage calculation was that produced by resonance scattering. As discussed in Section 4 resonance scattering of U-238 is not included in the HAMMER multigroup library, since it is treated in the resonance calculation. However, in the final B-1 leakage treatment, when the resonance capture and fission cross sections have already been defined, resonance scattering should be included as well. In order to test its effect average group resonance scattering cross sections were introduced into the computation at this stage. They increased  $k_{eff}$  by about 0.5 percent without affecting the other integral parameters significantly. However, the magnitude of the change in  $k_{eff}$  should be regarded as an upper limit since it refers to unshielded resonance cross sections. Shielding would certainly be significant, although possibly less pronounced than in the case of capture. Consequently, the results would be much closer to those in which resonance scattering is omitted altogether and which were discussed in Section 10.

In conclusion, it may be said that after reduction of the U-238 shielded resonance integral by about 0.4 barns quite good agreement of the parameters  $\rho_{28}$ ,  $\delta_{25}$ ,  $\delta_{28}$ , and C with experimental values is obtained. These parameters were measured at the center of the core. The values of  $k_{eff}$  are less than unity, especially for the tightest lattice where the discrepancy remains more than 1 percent. The multiplication factor relates to the assembly as a whole and part of its underprediction may be due to the fact that asymptotic reactor theory in the lattice analysis code is compared with experiments on assemblies with rather small cores.

#### Appendix

Construction of Probability Tables in the Unresolved Resonance Region

The RESEND program<sup>(4)</sup> prepares a library in which the ENDF/B File 2 resonance data are converted to cross sections and added to the contents of File 3. In the unresolved resonance region average unshielded cross sections are calculated at the energy points at which the average resonance parameters and the statistical distributions of the neutron widths and resonance spacings are specified.

To obtain the actual cross sections in a Monte Carlo calculation the average cross sections must be multiplied by a random number selected in accordance with the relevant probability frequency functions  $P(\sigma)$ . Levitt<sup>(7)</sup> calculated the integrals of these functions over specified cross section intervals (bins). The coice of the required random number is then a simple matter in a Monte Carlo program when interpolation within each bin is applicable.

The probability per unit cross section interval that its value is  $\sigma_{\textbf{y}}$  is given by

$$\mathbf{P}(\sigma) = \frac{1}{\Delta \mathbf{E}} \int d\mathbf{E} \, \delta \left[ \sigma - \sigma(\mathbf{E}) \right] \tag{A.1}$$

The numerator of this expression sums all elementary energy intervals in  $\Delta E$  for which  $\sigma(E)$  precisely equals  $\sigma$ . It leads to the correct average and higher moments of  $\sigma(E)$  in  $\Delta E$ . Actually when the cross section has a complicated resonance structure,  $P(\sigma)$  also exhibits considerable structure, since it is large at the maxima and minima, and small when the cross section changes rapidly. In addition  $P(\sigma)$  depends on the interval  $\Delta E$  which has been selected, unless it contains a very considerable number of resonances for each J sequence, and on end-effects which may arise from strong resonances near the limits of  $\Delta E$ .
In the unresolved resonance region one may, however, specify probability tables averaged over many resonance ladders which are free from these difficulties. A ladder may be constructed from the average resonance parameters and the statistical distributions of neutron widths and resonance spacings specified at energy E. If this ladder is placed in a random manner with respect to E the cross sections at this energy can be calculated. Averaging this process over many such ladders leads to the probability table at energy E.

In practice only the resonances closest to E contribute to the cross sections. Assuming the Wigner distribution of resonance spacings

$$p(x) \approx \frac{\pi}{2} x e^{-\frac{\pi x^2}{4}}$$
 (A.2)

the actual spacings of successive resonance is < D > x where x is selected from this distribution. However, the probability that E lies between a resonance pair whose peaks are separated by  $D_0$  is also proportional to  $D_0$ itself, since the ladder is placed randomly with respect to E. Consequently, in constructing the ladder  $D_0$  may be selected first as  $D_0 = < D > y$  where y is a random number chosen from the probability frequency function

$$q(y) = \frac{\pi}{2}y^2 e^{-\frac{\pi y^2}{4}}$$
 (Modified Wigner Distribution) (A.3)

The nearest resonance pair is then placed on the energy scale so that E lies at a random location between these two peaks. More resonances can then be located on the energy axis above and below the pair closest to E at separations  $< D - \alpha$ . The reaction widths of the resonances are obtained by multiplying their average values by random numbers selected from the appropriate  $x^2$  dis-

- 251 -

tributions. The cross sections at E are finally obtained from the neighboring resonances in the ladder after Doppler Broadening. For single level Breit Wigner cross sections, this can be done by means of the line shape functions.

The above construction of ladders and probability tables is consistent with the usual formula for the average resonance cross sections: The principal contributions to the cross sections at E come from the nearest resonance pair the peaks of which are separated by  $D_o$ . This corresponds to an average level density of  $1/D_o \simeq 1/ < D$  from Eqs. A.2 and A.3. Consequently, the average cross section at E becomes

$$<\sigma_{\mathbf{x}} > = \frac{\pi}{2} - \frac{\sigma_{\mathbf{o}}}{<\mathbf{D}} - < \frac{\Gamma}{\Gamma} \frac{\Gamma}{\mathbf{x}}$$
 (A.4)

if correlation effects due to more distant resonances are negligible.

Figs. 1 and 2 show capture and scattering cross section distribution functions  $\int_0^{\infty} P(\sigma') d\sigma'$  obtained by a code which uses the above algorithms. They refer to U-238 at 4 kev, the low limit of the unresolved resonance region. Three neighboring resonance pairs have been included in the cross section calculations for s-wave resonances and two pairs for each J sequence of the p-wave resonances. The effect of Doppler broadening is shown: for a given random number a smaller cross section is obtained at the low temperature in the resonance wings and the converse applies near the resonance peaks. The average cross sections are also compared with the RESEND values, Eq. A.4.

The code has also been used to determine the significance of cross section correlations by determining the cross sections at energy E-d as well as those at E. The correlated frequency function

$$\mathbf{P}_{\mathbf{d}}(\sigma,\sigma') = \frac{1}{\nabla \mathbf{E}} \int_{-\infty}^{\infty} d\mathbf{E} \wedge \left[ \sigma - \sigma(\mathbf{E}) \right] \wedge \left[ \sigma' - \sigma(\mathbf{E} - \mathbf{d}) \right]$$
 (A.5)

represents the double differential probability per unit cross section intervals that their values are - and ' for energy difference d. The conditional probability

$$P_{-,d}(-') = \frac{P_d(-,-')}{P(-)}$$
 (A.6)

expresses the chance per unit cross section interval that its value is  $z^2$ , if the cross section at an energy sugmented by d is -. In figures 3, 4, and 5 the distribution functions at E and E-d are shown for capture in U-238 at E=4 kev and d = 1,5,20 ev below this energy. In Fig. 3 there is strong correlation: When - is small (or large) there is a high probability that -' will elso be small (or large). At d = 5 ev the correlation is much less pronounced, and at d = 20 ev it has practically disappeared.

The figures provide quantitative evidence that cross section correlations at successive neutron collisions in the unresolved resonance region are insignificant if the neutron energy loss per collision exceeds the mean resonance spacing.

A Discussion of U-238 Resolved Resonance Parameters and their Influence on Capture Cross-Sections

> M. R. Bhat National Neutron Cross Section Center Brookhaven National Laboratory Upton, New York 11973

> > April 1975

In the following, the experimental data on the resonance parameters of the first four resolved resonances of U-238 will be reviewed. The purpose of such a review is (1) to estimate the errors in the resonance parameters and (2) to determine how far the parameters could be reasonably changed within the bounds determined by the experimental uncertainties in the thermal capture cross-section and the infinitely dilute resonance capture integral. To be specific, the effect of changing the gamma width of the individual resonances will be studied and its effect on the effective resonance integral determined.

### Resolved Resonance Parameters and their Error Estimates

The resonance parameters of the first four s-wave resonances of U-238 will be considered in detail as their contributions to the thermal capture cross-section and the dilute resonance capture integral account for about 90% of their experimental values. These are given in Table 1 along with the errors in these quantities as quoted by the experimenters and the type of cross-sections measured. If one of the parameters e.g.  $T_{\rm Y}$  is enclosed in paranthesis this indicates that the value was taken over from some other experiment and was not obtained as part of the analysis involved.

- 255 -

An examination of these data indicate that the neutron widths obtained by Radkevich<sup>(5)</sup> are consistently low for all the four resonances and lie well outside the range covered by other experiments. This may be due to some systematic error in this experiment and make the results suspect. If these numbers are left out one notices that in general  $\Gamma_{\rm v}$  show more of a spread in values than does In. Looking at these data sets it appears that the capture width of these resonances could have a value varying from resonance to resonance and it appears highly likely that it would lie between 22 and 26 meV. The recommended values in BNL-325<sup>(1+)</sup> for the first resonances are  $26 \pm 2$ ,  $25 \pm 3$ ,  $25 \pm 2$  and  $22 \pm 2$ . It is felt that the errors assigned represent a conservative lower limit and the uncertainty in the radiation widths are at least twice the values given. Though some of the authors claim errors of the order of 1% or less it is obvious that the systematic errors in these parameters are much larger than the quoted errors. The radiation widths for these resonances in the ENDF/B-IV (MAT = 1262) evaluation are 25.6, 26.8, 26.0 and 23.5 meV. The parameter  $\Gamma_n$  for these resonances have a narrower distribution and the recommended values in BNL-325 or the ENDF/B-IV evaluation appear reasonable. They are 1.5, 8.8, 31.1 and 25.3 meV respectively in ENDF/B-IV. In the following a value of  $\Gamma_{ij}$  = 24 meV will be assumed and the effect of lowering it by 9% to 22 meV on the various derived quantities will be studied.

### Changes in the Capture Width and their Effect on the Thermal Capture, Dilute Resonance Integral and Effective Resonance Integral

The thermal capture cross-section of U-238 has a value of 2.70  $\pm$  0.02 barns<sup>(16)</sup>; this is also the value used in the ENDF/B-IV evaluation (MAT = 1262).

The dilute resonance capture integral is generally accepted to be  $275 \pm 5$ barns<sup>(16)</sup>. Any changes that are made in the capture width will therefore have to be compatible with the errors in these two experimental values. As has been mentioned in the last section, the greatest uncertainty lies in our knowledge of  $\Gamma_{\gamma}$  for the various resonances. Hence, it appears to be of some interest to study the effect of varying  $\Gamma_{\gamma}$  for the individual resonances.

In considering these changes it will be assumed that the covariance between  $\frac{\gamma}{n}$  and  $\frac{\gamma}{\gamma}$  is identically equal to zero. The fractional change in the contribution of a particular resonance to the thermal cross-section is found to be approximately equal to the fractional change in  $\frac{\gamma}{\gamma_i}$ ; where  $\frac{\gamma}{\gamma_i}$  is the radiation width of the i-th resonance.

$$\frac{\Delta \sigma_{nYth}(i)}{\sigma_{nYth}(i)} = \frac{\Delta \Gamma_{Yi}}{\gamma_{i}}$$
(1)

Similarly, the fractional change in the contribution of i-th resonance to the dilute capture resonance integral is

$$\frac{\Delta \Gamma_{\rm Yi}}{\Gamma_{\rm Yi}} = \frac{\Delta \Gamma_{\rm Yi}}{\Gamma_{\rm Yi}} \frac{\Gamma_{\rm ni}}{\Gamma_{\rm i}}$$
(2)

where the symbols have the usual meaning. The effective or the shielded resonance integral (see Appendix) is a sum over terms of the type

$$I_{effi} = \frac{r}{2E_{ri}} \Gamma_{vi} \sigma_{oi} \sqrt{\frac{B_i}{B_i+1}}$$
(3)

each term for a resonance; where  $S_i = \frac{\Gamma_i}{K\Gamma_{\gamma i}} \frac{\sigma_p}{\sigma_{oi}}$ . Here  $\sigma_p$  is the potential

- 257 -

scattering cross-section and  $\sigma_{oi}$  the peak cross-section of the i-th resonance and K is defined in the Appendix. Differentiating the above expression we get,

$$\frac{\Delta I_{effi}}{I_{effi}} = \frac{1}{2} \frac{\Delta \overline{Y_i}}{\overline{Y_i}}$$
(4)

Looking at equations (3) and (4) one observes that a relatively large fractional change in the effective resonance integral can be achieved for a small change in the dilute resonance integral provided  $\mathbb{Z}_{ni} \ll \mathbb{Z}_{i}$ . This condition is fulfilled for the 6.67 eV resonance in U-238 for which  $\Gamma_{ni}/\Gamma_{i} \sim .06$ . Hence, it appears possible to bring about a substantial reduction in the contribution of the 6.7 eV resonance to the shielded resonance integral while keeping within the bounds of the error of 5 barns in the dilute resonance integral. However, such a reduction in  $\mathbb{Z}_{p}$  will also cause a decrease in the value of the thermal capture cross-section which is known to 1% or an error of 0.02 barns. In such a case, it may be possible to include a bound level so that its contribution to thermal capture makes up for the decrease caused by reducing  $\mathbb{Z}_{2^{n-1}}$  . The parameters of the bound level will have to be such that it does not in any way vitiate the 1/v shape of the low energy capture cross-section. It is found that a bound level of -20.0 eV can indeed be found which fulfills these requirements. Since the average spacing of the s-wave resonances in U-238 is about 18 eV; a bound level at -20.0 eV is consistent with it.

In Table 2 are shown the changes caused by decreasing the radiation width from 24 to 22 meV or by about 9%. These numbers show that a decrease of about 0.3 barns in the effective resonance integral of U-238 for a TRX-1 lattice may be

- 258 -

brought about for changes in the dilute resonance integral of 4.7 barns which is the same as the error in its value. The thermal capture cross-section will be reduced by 182 mb and this could be made up by including a bound level with a reduced neutron width of 0.75 meV and a  $\tau_{\gamma} = 23.5$  meV at 20.0 eV.

## Acknowledgement

Some of the questions discussed here came up at the time of the U-238 Capture Seminar held here on March 18, 1975 and my thanks are due to S. Pearlstein for suggesting that they be further investigated in a parametric study.

# Appendix

The following expressions were kindly supplied by Prof. W. Rothenstein; they give approximate formulae for the effective resonance integral  $l_{eff}$  for a metallic uranium rod of low enrichment.

$$I_{eff} = \frac{-}{2} \quad \frac{-}{E_r} \quad \frac{-}{4} \quad \frac{3}{5+1}$$

where  $\beta = \frac{\Gamma}{K_{\gamma}^{T}} - \frac{\frac{2}{p}}{\frac{2}{p}}$  (wide resonance approximation)

where  $E_r$  is the resonance energy and  $T_o$  the peak cross-section;  $T_p$  the potential scattering cross-section  $T_q$  and T are the capture and width of the resonance and

$$K = \frac{D\sum_{p}}{1-T} ; \sum_{p} = N\sigma_{p} = macroscopic potential scattering cross-sectionfor U-238; N = 0.047
$$D = diameter of fuel rod$$
$$T = transmission probability from rod to rod through themoderator in the lattice.$$$$

For the TRX lattices D = 0.983 cm. and
